As pointed out by him, the difficulty with the balanced protection is for the single-line operations, and in that case the impedance relay offers a very nice solution for a back-up protection. If it would be possible economically to justify putting lines in pairs, and only operating them in pairs, the balanced protection would certainly be the one to use.

I want to answer the two questions of Mr. Sleeper in regard to the zero time. That zero time is now at the minimum that we have been able to get, and that is 0.25 sec. for this zero voltage, and 200 per cent current. Now, as current goes up with zero voltage, that time will be reduced considerably.

In regard to the time delay introduced by the directional element, I did not point out that the voltage used on the directional element and the voltage used on the impedance element are not the same ones, so that, for a line-to-line fault, the voltage on the impedance element will never be reduced to less than line-to-ground value and, likewise, for a ground fault, the voltage on the directional element is a different one from the one on the restraining element, and there again, it would never be reduced to less than line-to-ground voltage.

Under those conditions, we have found that the additional time involved is something of the nature of two to three cycles, and is constant over the range of operation. In other words, the voltage is sufficiently high that variations in current do not make any appreciable variation, it is simply a constant addition of between two and three cycles.

In regard to Mr. Traver's remarks, the number of elements is perhaps higher than if straight overload relays are used. However, the only reason for using impedance relays is that you cannot always get the result you want with the other relay, and for that reason you have to justify some further complications in the system. If you could not justify them, if you could get the results you wanted with the simple system, the simple system would be the one to use.

In regard to inverse-time relays, there you introduce a variable that will have a very definite effect on the time of operation of the relays, whereas with the impedance relay the fault may vary over a considerable range without greatly affecting the time of operation of the various relays.

That brings up another point that Mr. Traver mentioned, that is the fact that, from the curves, he did not think that the time was constant and independent of current. If you look at these curves and take, for instance, 300 per cent current and 6¼ volts, you will find that is approximately 0.75 sec.; then going on and taking 600 per cent current, that is double the current and double the voltage, you will find that the time is very nearly the same, it might be a fraction of a second higher, and so on, out to practically 1000 per cent of the relay setting, the time rises a very small amount, not enough to affect the selectivity of the system to any great extent, and on very few systems, I think, is there more than a variation of 5 to 1 in the ratio of minimum and maximum short circuit, at any one point.

The matter of setting relays was mentioned by Mr. Traver. Subsequent to the publication of the instruction book that he saw, with the large number of tables, a different method of setting has been developed whereby any setting may be arrived at by the use of a simple formula and the setting obtained directly. Since that, a chart has been developed by means of which with a straight edge the setting may be arrived at without any calculations at all. The various tables are not used at the present time.

In regard to using the impedance relays in systems where other relays are already used, at the generating-station end is the only place where they will give any definite gain in result. Putting them at the generating-station end is exactly equivalent to cutting one step out of the loop. In other words, you reduce the total time by one step, and if the system then becomes large enough so that it is desirable to cut out another step it may be accomplished by putting them at the stations nearest the generating station.

In the first case mentioned by Mr. Edson where a change of direction of power flow takes place with the occurrence of a fault, the question is not merely of the directional contacts drifting open. In each case there will be a definite force tending to open or close the contacts depending on whether the fault current is flowing towards the station or away from it.

The use of the resistor in the directional element may have an advantage when potential is taken from condenser bushings since it somewhat reduces the burden.

In using low-tension potential and compensators it is only necessary to compensate for the drop of one transformer bank. As Mr. Edson points out, caution should be exercised in seeing that the switching is so arranged that one bank with compensators is always in service.

In the event of a high-resistance fault the $KY$ compensators when arranged as shown in Fig. 10 will still supply a voltage proportional to that existing in the high-tension side. The drop, however, may be so small that the relay will operate very slowly due to the high restraining voltage. In cases of this sort the current will also be considerably reduced and may not be sufficiently high to operate the relay. In this case its effect on the system will be small. Where this condition exists the system described in the first paragraph under Special Applications is recommended.

# Automatic Switching of Incoming Lines and Transformers Supplying Power to A-C. Substations

BY A. E. ANDERSON[1]
Associate, A. I. E. E.

***Synopsis.**—The early applications of automatic switching were confined principally to equipment which supplied or handled the outgoing power, such as conversion apparatus and outgoing feeders. As the field broadened and the capacity of the stations increased, it became necessary to provide for greater continuity of incoming power. In order to meet this requirement it has been customary to bring in two, and occasionally three, incoming lines.*

*It is the purpose of this paper to describe briefly some of the more common forms of this type of automatic switching. By making a few minor modifications of the schemes which are described it has been possible to control automatically a complete loop or ring system.*

*Balanced power or parallel incoming lines are quite common. Ordinarily two such lines are used, although as many as six have been contemplated. All lines are usually carrying power to the substation unless a fault has developed. When cleared of the fault, the line (or lines) is automatically replaced in service.*

*In the case of the preferred-emergency type of equipment, it is customary for one line (the preferred) to carry the substation load. The second line (emergency or standby) takes this load upon failure of the first line. The application of these units to a system usually determines the sequence of operation between the two lines. A few typical combinations are described and illustrated.*

*A brief description of automatic synchronizing and transformer switching has been included.*

## INTRODUCTION

The early application of automatic switching was confined principally to rotating machinery such as rotary converters and motor-generator sets. In the development and extension of automatic control, it was a logical step that attention should be given to the switching of a-c. incoming lines which supplied power to substations having a number of distribution feeders. These feeders were usually at 2300 volts and of the automatic reclosing type. The essential purpose of the incoming line equipment was to have two (or more) sources of power available, using one as the normal or preferred and the other as the emergency or standby.

A parallel development has been one which resulted in equipments suitable for controlling parts, if not all, of transmission systems, and load responsive switching of transformer banks. It can be seen that the field of application of this kind of equipment is very broad. This paper will be confined to the more common types.

At present a total load of over 500,000 kv-a. is being taken care of by these equipments. The voltages range from 2.3 to 132 kv., while the capacity per substation, so controlled, averages approximately 5000 kv-a., the lower limit being 1000 kv-a. and the upper is slightly in excess of 25,000 kv-a. It is felt that the application of these equipments will be greatly increased in the future. There are many substations at present that are being fed by one incoming line. Extension of the system in the future, and perhaps, in addition, the increasing importance of the load supplied by such stations may result in connecting these stations to another nearby line or lines. Again, a new or existing station may be called upon to supply a type of load where continuity of service is a primary consideration. The customary solution is to bring in another source of power through a second and sometimes a third incoming line. The use of two incoming lines for such installations is quite common. Another example of this type of equipment is in the automatic control of loop or ring systems, which, at times, require automatic synchronizing in addition to the usual control. Automatic supervisory equipment is sometimes used in conjunction with this form of control.

It is not the purpose of this paper to cover the various system protective features, since this is a subject in itself. Attention will be given to the operations performed by the automatic control from the point of the individual installation rather than the system in general. However, it might be well to point out in passing that the method used in applying protective devices to a system made up in part or in whole of automatic stations is not always the same as in the case of manual stations, even though the final result may be the same. With manual operation the next move is sometimes up to the operator. In the case of automatic operation after the protective or other relays have functioned, the remaining relays must be ready at once (if necessary) for further operation, or those which have just operated must reset automatically and be in readiness for a resumption of their former operation. This last feature requires not only a study of the resetting features of the various protective devices, but a study of the system as a whole, before and after a particular switching operation. Consequently, it may be found that different relays are used for automatic operation, although basically there may be no outstanding difference between such relays and those used for manual operation. The question of maintenance is another important factor. This feature requires greater reliability of relays used in automatic stations.

In addition to the different types of incoming lines there has been prepared a brief description of automatic synchronizing and transformer equipments. The application of these various forms of automatic switching

---

*Presented at the Regional Meeting of the A. I. E. E., St. Louis, Mo., March 7-9, 1928.*

is given under the various headings. Six common types of automatic switching are illustrated by one-line diagrams. These substations are assumed as feeding power to outgoing distribution feeders of the automatic reclosing type. Service conditions and many other local factors usually decide what type of equipment should be used.

### BALANCED POWER OR PARALLEL INCOMING LINES

A very common form of incoming lines are the parallel or balanced power as illustrated in Fig. 1.

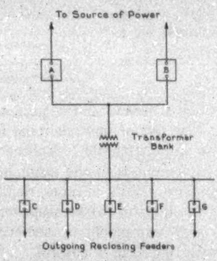

FIG. 1—ONE LINE DIAGRAM. TWO-BALANCED POWER OR PARALLEL INCOMING LINES

Normally, both *A* and *B* are closed. *A* or *B* trip on unbalanced power and reclose on voltage restoration.

This substation is fed from the same generating station by means of two lines of practically equal impedance. In case of a current unbalance as caused by a fault on one line, the oil circuit breaker feeding this line from the generating station is tripped, as well as the corresponding breaker at the substation.

The substation breakers reclose only when three-phase voltage has been established on the incoming line for a definite time. This means that the corresponding generating station breaker must be reclosed either manually or automatically and attempt to reestablish service on the line. In case of short circuit conditions, only a few such attempts are made and consequently the substation breaker does not reclose. In this manner the brunt of the overload duty is thrown on the generating station breaker. Operating experience has shown that one breaker operating on the ordinary reclosing cycle will reestablish service or lock-out and that there is little to be gained in putting a second breaker through this cycle under conditions which caused the first breaker to lock-out.

The three-phase voltage indication for a definite time shows that the fault has been removed and the line clear. The time delay is used in order to permit any protective relays to operate before the substation breaker is closed. At times it also permits certain loads to be applied gradually in a step-by-step sequence. At the expiration of this timing action the substation incoming line breaker closes and normal connections are restored.

Occasionally it is desired to use single-phase voltage on the incoming line as the indication for closing. Cases may be found where one line wire has grounded in such a way that no fault current would be obtained when the generating station breaker closed, yet due to the fact that the voltage indication was taken between the two good line wires, the incoming line breaker at the substation would reclose. Upon reclosing, a fault current would be obtained. This may be readily seen if it is assumed that the wire breaks at an insulator in such a way that the grounded end is away from the substation, and normal three-phase voltage is maintained on the substation bus by means of the other incoming line.

Therefore, due to the fact that single-phase voltage indication may result in improper reclosing action on the part of the substation breaker, it has been found advisable, when single-phase voltage indication is used, to add a relay which will permit the breaker to reclose a certain number of times in a predetermined time.

### PREFERRED-EMERGENCY INCOMING LINES FROM SYNCHRONOUS SOURCES

This type of equipment may be considered as a modification of that just described. Due to the fact that the two incoming lines, Fig. 2, are of different impedance, enough current unbalance might be obtained (to operate any protective relay) if both breakers *A* and *B* were closed for any appreciable time. In addition, any connected load on these lines may require that both lines be normally disconnected from each other. Consequently, the load at this substation is normally supplied from one line called the preferred or normal. The other line, called the emergency or stand-by, is used only in case it is in good condition and voltage

FIG. 2—ONE LINE DIAGRAM. TWO PREFERRED-EMERGENCY INCOMING LINES FROM SYNCHRONOUS SOURCES

Normally, either *A* or *B* is closed, and trips on voltage failure, provided voltage conditions are proper on the other (emergency) line. Restoration of voltage to the preferred line results in retransfer of the load to that line. Under certain conditions *A* and *B* may be closed simultaneously for a short interval. Either line may be made the preferred has failed on the preferred line. The choice as to which line is the preferred or emergency depends on local conditions, and can readily be made by a transfer switch.

Undervoltage releases on the oil circuit breakers are not recommended for this service. Their principal disadvantage lies in the fact that if they are instantaneous in action, they are apt to drop out on short-voltage "dips." Again, both sources may become deenergized which results in tripping a breaker when nothing is usually gained by such an operation. A subsequent return of voltage finds both breakers open and some time will be required before reconnection may be made. If time delay action is provided on the undervoltage releases, it is then found that there is a number of operating conditions that require the addition of suitable contacts. It has been found that such contacts can be placed more satisfactorily on a panel-mounted device than on an undervoltage release. These panel-mounted devices together with potential trip coils, energized from the "opposite" line, give the desired operation.

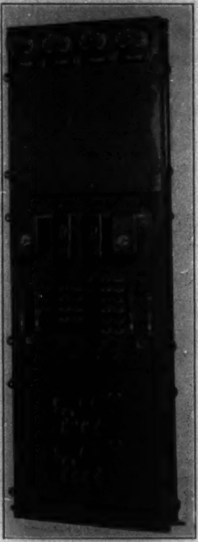

FIG. 3—PANEL-MOUNTED DEVICES FOR CONTROLLING PREFERRED-EMERGENCY INCOMING LINES FROM SYNCHRONOUS OR NON-SYNCHRONOUS SOURCES, AS WELL AS FOR CONTROLLING NON-PREFERENTIAL INCOMING LINES

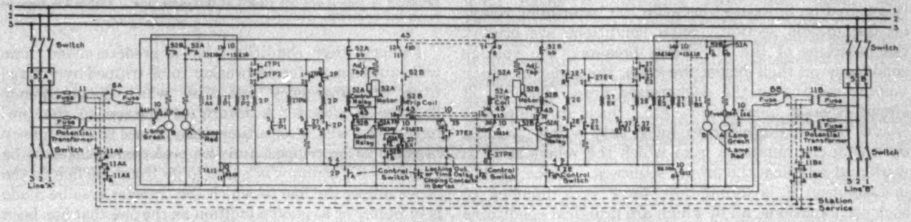

FIG. 4—ELEMENTARY DIAGRAM FOR TWO PREFERRED-EMERGENCY INCOMING LINES FROM SYNCHRONOUS SOURCES

Fig. 3 illustrates the necessary panel-mounted devices for the control of such equipment. This panel may be used for controlling a-c. or d-c. operated oil circuit breaker mechanisms. On the top section are mounted four undervoltage relays. Two relays are used for each line, one for each of the two phases. Fig. 4 gives the elementary diagram of control for two preferred-emergency lines from synchronous sources.

The general sequence of operation of such an equipment is as follows:—Assume that the preferred breaker is closed, then upon occurrence of undervoltage on any phase or phases of the preferred line, its undervoltage relays start to drop out and after a time delay will close a set of contacts. Operation from this point on depends on the condition of the emergency line. In other words its voltage conditions must be satisfactory, otherwise there is little to be gained in making a transfer. In order to make a transfer all three phases of the emergency line must be in good operating condition as determined by its respective voltage relays.

Assume conditions are thus far satisfactory for a transfer. A timing relay with a relatively longer setting is placed in action. This type of relay, as shown at the extreme left and right at the top of the middle section, Fig. 3, is energized from the emergency line, but is controlled by the undervoltage relays on the preferred line. The timing relay is used to prevent a transfer due to momentary voltage "dips" and also to allow any protective scheme (especially at the source) to operate and clear a fault which may cause such "dips" on the supply source.

At this point it might be well to state that as the result of a number of tests it has been found that the ordinary oil circuit breaker mechanism does not operate fast enough to make a successful transfer which will result in holding in all of the so-called "instantaneous" undervoltage releases commonly used with induction motor starters. At times 50 per cent of such releases have been held in, where the oil circuit breaker mechanism has been purposely speeded up. Moreover, if a group drive is used, it seems better to slow up the transfer (and bridge the usual momentary voltage "dips") and drop off all of the induction motors. This also results in less strain and longer life to the transfer equipment.

If undervoltage conditions still exist, usually from 5 to 10 sec. or over, then the preferred breaker is tripped. This tripping action is obtained by voltage from the emergency line. As soon as the preferred breaker opens the emergency breaker is closed. The control is so interlocked that when a transfer is made in this direction the preferred breaker must be open before the emergency breaker can close. The reasons for this are that a fault may exist on the preferred line and if both breakers were closed simultaneously this fault would be reflected to the emergency line, which would probably trip the breaker at the supply source and result in a loss of voltage and no means of opening the preferred breaker. Over-current protection on these equipments is usually dispensed with and potential tripping only is used in connection with the transfer operation.

Consequently in making the above transfer the load is momentarily dropped. However, if voltage remains on the emergency line and also returns to the preferred line for a definite length of time, then the preferred breaker is closed after which the emergency breaker is immediately opened. This temporary overlap is so short that protective relays will not operate, and results in a retransfer without dropping the load.

There is a number of other conditions that such an equipment has to meet. These requirements to a certain extent account for the presence of the two relays in Fig. 3, located between the two-timing relays on the middle section. Such conditions are briefly: the positions of the oil circuit breakers, the voltage conditions on their respective lines, the order in which voltage returns to the deenergized lines, type of oil circuit breaker mechanisms, etc. Such an equipment would probably appear to have only a few possible operating combinations from which the relays have to work and establish the proper sequence. Upon further investigation it is found that there is a number of such combinations, all of which are practical conditions and which can be taken care of by proper connections or choice of devices.

This type of equipment is usually furnished with two transfer switches. One is used to select the "preferred" and "emergency" sources from the two incoming lines. The other is used to enable the equipment to be operated entirely automatically or entirely manually. These two latter functions are kept independent of each other.

As mentioned above, either a-c. or d-c. operated oil circuit breaker mechanisms may be used with standard oil circuit breakers. A small number of auxiliary switches is included for interlocking purposes.

The equipment controlled by the devices as shown in Fig. 3 was used to supply power to an automatic railway substation. The two contactors on the bottom section supplied control power to the machine devices and have no direct function with the preferred-emergency unit.

## PREFERRED-EMERGENCY INCOMING LINES FROM NON-SYNCHRONOUS SOURCES

An application of incoming lines of this type is shown in Fig. 5. It will be noted that the two incoming lines are assumed to be out of synchronism at all times. Therefore, breaker *A* must be open before *B* can close, and vice versa. If this is not done, then the incoming line equipment will connect two generating stations which may be out of synchronism. Either line may be made the preferred as explained above.

Outgoing Reclosing Feeders

FIG. 5—ONE LINE DIAGRAM. TWO PREFERRED-EMERGENCY INCOMING LINES FROM NON-SYNCHRONOUS SOURCES

Normally, either *A* or *B* is closed, and trips on voltage failure, provided voltage conditions are proper on the other (emergency) line. Restoration of voltage to the preferred line results in a retransfer of the load to that line. Breakers *A* and *B* are not closed at the same time. Either line may be made the preferred

Undervoltage conditions for a predetermined time will cause the preferred breaker to be tripped by voltage from the emergency line after which the emergency breaker is closed. A return of voltage to the preferred line, will, after a time delay, cause the emergency breaker to be tripped and the preferred breaker to be closed. No attempt is made to go from one line to the other unless the line to which the transfer is to be made is in better or as good condition as the one that has been supplying power previously.

If both breakers are open and voltage returns to one line, the breaker on that line will close. If both breakers are open and voltage returns simultaneously to both lines, the preferred breaker will be closed.

Although it is assumed that the supply sources are usually out of synchronism, there may be cases where a tie-in between these sources may result in the two lines being in synchronism. Consequently, at such times a retransfer can be made from the emergency to the preferred line without dropping the load. Such switching can be made when proper voltage conditions exist on both lines. In order to make certain that these voltages are of the proper phase relation it is necessary to add a synchronism check relay to the customary devices. If the conditions are such that this relay does not operate then the emergency breaker must open before the preferred breaker can close. If the conditions are satisfactory, then the preferred breaker is closed, after which the emergency breaker is tripped.

With the above exceptions of sequence and application, the preferred-emergency type of incoming lines from non-synchronous sources, operate similar to those from synchronous sources.

Two load responsive transformer banks are also shown in Fig. 5. One bank carries the substation load during light load periods. The second bank is connected when the load on any one phase increases to a predetermined value. When the load on all three phases decreases to another predetermined value the second bank is disconnected.

The indication for bringing on or taking off the second bank is obtained from current transformers connected in the line. Where two or three power transformers are used it is found advisable to parallel the current transformer secondary circuits and totalize the current on each phase. This permits the use of a fewer number of master relays with a resulting simplification of relay calibrations. If one set of relays is used for each bank it becomes necessary to provide a gap in the relay calibrations, in order to avoid having two sets of relays calling for opposite switching action.

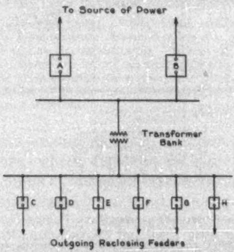

FIG. 6—ONE LINE DIAGRAM. TWO NON-PREFERENTIAL INCOMING LINES

Normally, either *A* or *B* is closed and continues to remain in this position until its voltage fails and proper voltage conditions are present on the other line. No preference is given to either line under a majority of conditions

Differential and thermal protection are ordinarily provided. Upon failure of one bank it is immediately disconnected and locked out, the remaining bank then takes its place and no further load responsive switching is performed until the lock-out relay or relays are manually reset. This enables the equipment to be inspected and the cause of failure ascertained before the unit is replaced in service. Either bank may be made the "leading" or "trailing" by means of a transfer switch.

### NON-PREFERENTIAL INCOMING LINES

At times it has been found advisable to allow either incoming line to feed the load as long as proper voltage conditions exist on its line regardless of conditions on the other line. If voltage fails on this line and conditions are satisfactory on the other, then its breaker will trip and the other close. The other line continues to feed power to the load regardless of a return of voltage to the first line. Due to the fact that a breaker can remain closed as long as voltage remains on its line and no preference is given under a majority of conditions, such forms of incoming lines are called "non-preferential." No transfer switch is necessary in order to establish preference. A certain amount of preference is obtained by the relays in order to take care of cases where both breakers are open and voltage returns to both lines practically simultaneously. In order to secure positive closing action in such a case, one breaker must be given preference over the other. Fig. 6 gives a one line diagram of this type of equipment.

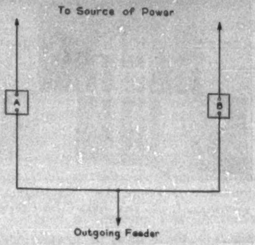

FIG. 7—ONE LINE DIAGRAM. TWO PREFERRED-EMERGENCY INCOMING LINES COMBINED WITH OUTGOING RECLOSING FEEDER

Normally, either *A* or *B* is closed and trips on voltage failure provided voltage conditions are proper on the other (emergency) line. Restoration of voltage to the preferred line results in a retransfer of the load to that line. *A* and *B* may be closed simultaneously for a short interval, depending on whether or not the two incoming lines are in synchronism. A limited number of reclosures is available in case of overload conditions

Due to the fact that one breaker is always open before the other can close, these equipments may be connected to synchronous or non-synchronous sources.

### COMBINED RECLOSING AND PREFERRED-EMERGENCY INCOMING LINES

Another common application is one in which two preferred-emergency incoming lines supply only one outgoing feeder. Overload protection is provided so as to trip whichever breaker is closed. If overload conditions persist, a certain total number of reclosures is permitted, after which the equipment is locked out. Fig. 7 illustrates the connections of such an equipment into a system. Fig. 8 illustrates an outdoor unit for such service. Such a unit is a combination of two incoming lines and one outgoing reclosing feeder.

Undervoltage conditions are taken care of in practically the same manner as the above preferred-emergency units. The combined equipment can be used for synchronous or non-synchronous sources and can also be made non-preferential.

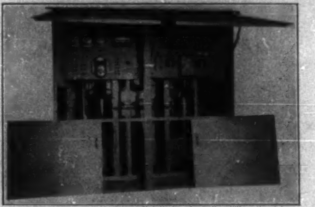

FIG. 8—COMBINED OUTDOOR A-C. RECLOSING FEEDER AND INCOMING LINES FOR 4000-VOLT CIRCUIT

## PARTIAL AUTOMATIC PREFERRED-EMERGENCY INCOMING LINES

A limited form of incoming line equipment is obtained by using one manually operated and one motor-operated breaker. The manually operated breaker is connected to the preferred line while the motor-operated breaker is connected to the emergency line.

Upon failure of voltage on the preferred line, its breaker is tripped after which the emergency breaker is closed. The equipment remains in this position until the retransfer is made manually.

A disadvantage of this type is that the emergency line may subsequently fail with its breaker closed and voltage return to the preferred source. Since the preferred breaker is manually operated it is necessary to wait for the arrival of the operator or inspector to effect the retransfer.

## AUTOMATIC SUBSTATIONS SUPPLIED BY MORE THAN TWO INCOMING LINES

Fig. 9 shows a one line diagram of an automatic station that is supplied by a number of incoming lines with their respective transformer banks. Line *A* and its associated transformer are the emergency and take the place of any line or transformers that have failed. Lines *B*, *C*, and *D* are the normal sources of power.

Normally line *D* and its associated transformer feed the low-tension bus sections which are now tied together. Whenever sufficient load demand occurs the second bank is brought on and the first bank carries only its section of the bus with its connected outgoing feeders. Continued load demand brings on the third bank with the same resulting connections. The low-tension bus is now completely sectionalized and each incoming line feeds its share of the outgoing feeders direct from the generating source. This results in radial or stub feed direct from the source to the load and also in a simple relay protective scheme.

If any line or bank fails, it is taken out of service and replaced by the emergency line. The remaining lines (in good condition) feed their share of the load direct as in the case of switching under normal conditions. The relays make the proper set up, after which the panel-mounted drum controller completes the required switching operation. The use of a drum controller for such equipment greatly decreases the number of contacts necessary on the relays and also results in a positive sequence of operation.

A total capacity of 27,000 kv-a. is handled by the automatic switching equipment in this station. The outgoing reclosing feeders in this particular installation are 2540/4400 volts using single-pole breakers with independent mechanisms and reclosing relays.

## AUTOMATIC TRANSFORMER LOAD RATIO CONTROL EQUIPMENT

Automatic switching equipment has been recently applied to transformer tap changing (under load). When two banks are used, either bank may be operated automatically or manually and when automatic may operate from individual or common master elements.

FIG. 9—ONE LINE DIAGRAM. THREE INCOMING LINES WITH LOAD RESPONSIVE TRANSFORMER BANKS TOGETHER WITH EMERGENCY INCOMING LINE AND TRANSFORMER BANK

Normally, *D* and *H*: *I*, *J*, and *K* are closed. As substation load is increased *C* and *G*, and *B* and *F*, are closed (successively) as required. Low tension bus is sectionalized (by opening *I*, *J*, or *K*) whenever two or more banks are operating, giving radial feed from generating station to load. As the load decreases the reverse operation takes place. On occurrence of line or transformer failures all lines and respective transformers in good condition feed their corresponding low tension bus sections, giving the above mentioned radial feed. The emergency line and bank (Breakers *A* and *E*) replace any defective line and bank

To adjust the line voltage in accordance with the changing load, the high-voltage windings have eleven taps of 2½ per cent each. To permit a change of taps without interrupting the load, a part of the high-tension winding is made in two sections, normally operating in parallel and dividing the load equally. Each of these winding halves is connected to an eleven-point ratio adjuster (Fig. 10), and the resulting circuits brought out of the transformer tank to two three-pole oil circuit breakers.

Consequently, it is possible during the tap-changing period to open circuit one section in each phase, and change the voltage tap in this open-circuited section while the other section temporarily carries the entire load of the transformer. Copper of ample cross-section and the very short transition period permits this to be done. The same change is then made in the second half. The entire change from one voltage to the next requires only 8 sec. For brief periods (less than 1½ sec.), when both breakers are closed but the two ratio adjusters are one tap apart, an internal circulating current exists, which, however, is kept within predetermined limits by sufficient inherent reactance in the transformer windings.

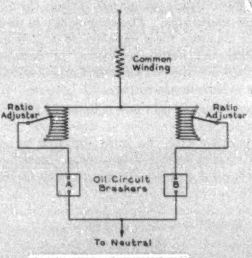

FIG. 10—ONE LINE DIAGRAM. LOAD RATIO CONTROL

Normally, *A* and *B* are closed. When voltage correction is required, as determined by suitable master element, breaker *A* is opened and corresponding ratio adjuster moves one point. Breaker *A* then closes and breaker *B* opens, followed by its corresponding ratio adjuster moving one point and in the same direction as movement of other ratio adjuster. Breaker *B* then closes. This sequence is continued as long as necessity for voltage correction is indicated

A motor-operated mechanism mounted on the transformer truck insures a properly timed operation of the internal ratio adjusters and the external circuit breakers. It is essential that the three corresponding ratio adjusters of the three phases move simultaneously from one tap to the next; therefore, these ratio adjusters are mounted together on the same shaft with full-phase insulation between them. Turning the driving shaft of this gear train one complete revolution will first change one set of three adjusters one step, then lock this set, and then turn the second set one step. Provisions are included also, so as to make certain that both sets change their taps the same amount in a predetermined time.

Contact-making voltmeters do away with any manual starting of the mechanism. If the line voltage deviates from a set value for a predetermined time, the tap-changing mechanism is automatically put in motion in one direction or the other to bring the voltage back to normal.

Two contact-making voltmeters are used on each of the two transformers, one adjusted to respond to a narrow range of voltage variations, while the other one is set for much wider differences in voltage. If the line voltage rises or drops only slightly, and if this condition persists for a predetermined length of time, the transformer will shift to the next proper tap. If, on the other hand, a considerable rise or drop occurs, the second contact-making voltmeter will respond, and will cause immediate adjustment without any time delay.

### AUTOMATIC SYNCHRONIZING OF INCOMING LINES

In general, there are two conditions under which an incoming line should be synchronized with the bus. One condition is where two sections of a system are already tied together at some other point. This means that the two voltages, at the open breaker terminals, are stationary with respect to each other, but may have a certain phase displacement due to circuit conditions.

In case two sections of a system are cut apart it will be found that the two voltages at the open breaker terminals will be rotating with respect to each other at a frequency equal to the frequency difference between the two generating sources. The equipment in the automatic substation has no control over the governors in either generating station, so that the closing operation of the breaker is determined by other factors which are: first, the frequency differential must be less than a certain value and secondly, the breaker closing impulse must be given enough ahead of synchronism so as to enable the breaker to be closed when the point of synchronism is reached, in other words, at "12 o'clock."

The calibration of the synchronzing relays for the two different operating conditions is such that one is inoperative under conditions under which the other functions.

It has been found advisable to use a separate synchronizing relay combination for each breaker. Different breakers have different closing characteristics, and even though a number of breakers could use a common synchronizing relay it has been found that the resulting scheme would be more complicated, less flexible, and more expensive than the individual control.

## Discussion

**E. L. Hough:** At the present time, there are few things that cannot be done with automatic switching equipment, and it is usually a question of proper economics in applying automatic control.

In checking over Mr. Anderson's figure of 500,000-kv-a. capacity being taken care of by incoming equipment, it would appear that this figure is low. We have in St. Louis approximately 100,000 kv-a. in automatic reclosing equipment, which are supplied by automatically switched incoming lines. I believe Kansas City has approximately the same amount.

Mr. Anderson has stated that operating experience has shown that one breaker operating on the ordinary reclosing cycle will reestablish service or lock-out. An additional point, that Mr. Anderson really did not intend to bring into this paper, which might be well worth thinking about, is the reclosing of cable circuits. Usual experience has been that after an outage on a cable, if a single reclosure does not restore service additional reclosures will not do so. It seems we should check up and find out if we would not be better off with oil circuit breakers, etc., if allowed only one closure on cable feeders.

Two different types of line-switching equipment for lines from synchronous sources are mentioned, one being the preferred-emergency equipment used where the lines are of different impedance. Where a feeder is spread out over the city to tap into other stations serving as an emergency feeder for all of them, the reason for making equipment "preferred-emergency" rather than "parallel-line" may be that it is undesirable to overload the emergency source rather than because of different line impedance.

Very frequently, the first step in the city distribution station is the use of preferred-emergency switching on two lines, and the second step would be the parallel operation of the lines. This is something that should be considered when originally designing the stations,—that is, do not design the equipment as suitable only for preferred-emergency service, but keep in mind that, some day, it may be desirable to operate the two lines in parallel.

Mr. Anderson has called attention to *load-responsive* switching of transformer banks. This is a subject that deserves further study, because there are real savings that can be made in taking transformer banks off the line at the time of light load. However we must consider the apparatus, and see that it will not be damaged by standing idle.

**Chester Lichtenberg:** Three points in Mr. Anderson's paper might be advantageously enlarged upon. On the first page appears the statement: "Consequently, it may be found that different relays are used for automatic operation."

It is a quite common occurrence to have relays applied on the basis of manual-operation experience. Then when the relays fail to function in automatic switching service, the relays are blamed rather than the application. Time and again it is found that relays in automatic stations are required to give a higher degree of service. Nobody is present to substitute for them when they do not function. They must go through their functions completely and of their own account. This hint in Mr. Anderson's paper looms large to those who have had experience in the application of manual relays to automatic station service.

We have preached for a number of years that maintenance and inspection are really the basis of successful automatic operation. Operators who are most successful with them find that a simple system of inspection and maintenance will result in a class of service equal to if not better than most manually operated stations.

The last paragraph in the paper is of even greater importance:

"It has been found advisable to use a separate synchronizing relay combination for each breaker. Different breakers have different closing characteristics, and even though a number of breakers could use a common synchronizing relay, it has been found that the resulting scheme would be more complicated, less flexible, and more expensive than the individual control."

We have tried to combine the necessary functions for each operation in one case or under cover, thereby reducing the number of devices per breaker. This emphasizes Mr. Anderson's point of a more simple system of connections.

**O. J. Rotty:** (communicated after adjournment) Mr. Anderson describes six different types of automatic switching for the supply lines to a-c. distribution substations. The most desirable type for any particular application depends upon many factors and must be determined for the individual case.

However, it is often desirable in the growth of a station or the development of a system to change the control of the incoming lines from one switching scheme to another. As a rule, this change must be made without any shutdown, and preferably without any crippling of the automatic functions. To accomplish this it is necessary to design the original scheme rather flexibly and as nearly as possible on a "unit" basis.

In the substations at St. Louis, we have adopted a design as standard which provides for two intermediate schemes of control before attaining the ultimate development. The stations are laid out initially for 7500-kv-a. capacity with two incoming lines, either one of which may be made the "preferred line," the other standing by as the "emergency line." They are from sources which may not be synchronous, but are provided with synchronism-check relays to permit tying them together on certain transfer operations. The second step in the development of the stations provides for a capacity of 11,250 kv-a. with the two lines mentioned before operating in parallel. After an interruption, either line is automatically reclosed upon the appearance of synchronous voltage.

The third and final development is for 15,000 kv-a. capacity with three incoming lines, two of which are "preferred" and operating in parallel with the third standing by as the "emergency." The control scheme is laid out so that the change from the first to the second step is carried out by the attachment of two jumpers and the removal of one 2-pole knife switch. The change from the second to the third step requires no additional apparatus nor rewiring of the two original lines and requires only the addition of the apparatus for the third or new line.

In this way it is possible to expand the station with practically no rewiring and with the least possible disturbance to normal operation.

**A. E. Anderson:** Mr. Hough seems to think that I dropped off a cipher, but I do not think I have. The value might be increased to 750,000 kv-a., or in that neighborhood.

For the protection of cable feeders, we have devised a scheme whereby the value of over-current will determine the reclosing cycle. In case the fault occurs from phase to phase, the particular maximum value of short-circuit current will place a reclosing relay in operation, which gives a certain cycle having longer time intervals than if the fault occurs from phase to ground.

This paper deals with some of the more common forms of incoming line switching. There is practically an infinite number of combinations that might be applied in service, all of which are more or less dependent on the particular conditions of the system, load, and many other factors that are more or less out of the control of the manufacturer.

I believe Mr. Lichtenberg has emphasized sufficiently the point of maintenance and characteristics of relays for automatic switching equipment. The types of equipment described in the paper are more or less flexible, some of the basic schemes—at least, we consider them basic—we can elaborate on and take care of a large number of combinations. It takes just a slight departure, here and there, in most cases, to give the desired operation.

# Improvements in Moderate Capacity Oil Circuit Breakers

BY J. B. MacNEILL[1]
Associate, A. I. E. E.

***Synopsis.***—*The increased duty requirements of power station service require circuit breaker design to give maximum interrupting capacity in a minimum of space. Compact, relatively high-power breakers having all three poles in a single round tank have been designed, which, in addition to increase in the rating for a given space, give improved performance over types previously available. The relations of the current-carrying loops inside the breaker and the diversity factor afforded by the common oil volume and air space give superior results in operation. This type of design permits use in current ranges where decreased arc energy, as compared to power handled, can be secured.*

* * * * *

THE desirability of getting increased circuit-breaking capacity in a given space arises frequently in rapidly growing power systems. There have been many cases where the oil circuit breaker has been the "neck of the bottle" in limiting power that can be handled on a switch house layout. The bus itself, disconnecting switches, and other elements may be entirely adequate to handle increased power, but the circuit breaker may present severe limitations.

It is only natural that operators and manufacturers alike should be interested in the development of an oil circuit breaker to handle a maximum power in a minimum of space. To do this, it is obvious that the combination of a three-pole breaker in a single round tank should receive consideration because of the possibilities of embodying in such a type the features that are used on high-power multiple breakers. A round tank is not in itself essential; in fact, any tank giving proper clearances and strength is sufficient. However, the ease with which necessary strength with minimum material can be obtained in a round tank with a dish bottom and a dome-shape cover, will be obvious.

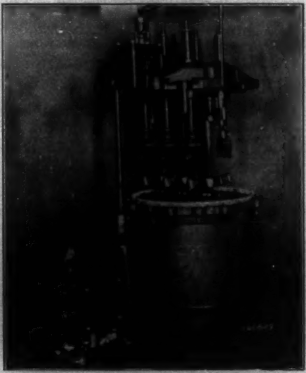

FIG. 1—THREE-POLE BREAKER IN SINGLE ROUND TANK SHOWING CONDENSER TERMINALS, CONTACTS IN OPEN POSITION, TANK REMOVED, AND ELECTRIC OPERATING MECHANISM

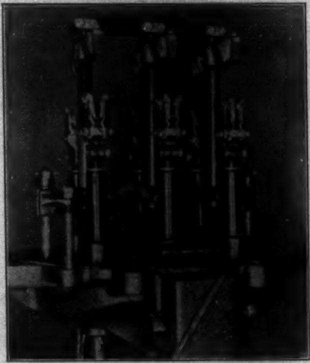

FIG. 2—THREE-POLE CIRCUIT BREAKER IN SINGLE ROUND TANK SHOWING CONTACT AND CROSS-BAR CONSTRUCTION WITH TANK REMOVED

In the past, objections have been raised in this country to the idea of multiphase switching in a single tank where considerable power is used. Many operators preferred isolation of the pole units from each other in separate cells so that in case of failure of one pole, fire and oil throw would have less chance to involve other phases. There was also the thought that when several phases were handled in a common volume of oil the chances for arcs getting together were increased. Manufacturers have, therefore, not found it generally desirable to depart from the conventional multiple single-pole arrangement for high-power work, because by so doing they would have to handle two types where one would do the work.

Recently, however, there has been an increasing

---

*Presented at the Regional Meeting of the A. I. E. E., St. Louis, Mo., March 7-9, 1928.*

number of stations where space is at a premium or where cell structures have already been built and are too small to allow ordinary breakers to handle present power demands. There has also been a demand in the smaller capacities for breakers that throw minimum amounts of oil and gas and, where the outlet of the breaker can be piped away from the structure with assurance, that such oil and gas will not be released in the cell structure itself.

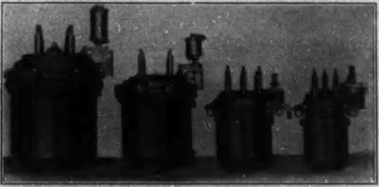

FIG. 3—FOUR SIZES OF THREE-POLE SINGLE-THROW OIL CIRCUIT BREAKERS HAVING ALL POLES IN SINGLE CYLINDRICAL TANK

The breaker shown in Figs. 1 and 2 was designed in 1922 to take care of the type of service referred to. It is a 20-in. diameter, round tank three-pole breaker embodying in a small space the general features of high-power breaker construction. The tank structure has a high ultimate strength resulting from steel construction throughout. It is equipped with a muffling device to separate the oil from the gas as it leaves the tank structure, and so arranged that the gas can be piped away—thus preventing the possibility of gas explosions in the switch cell.

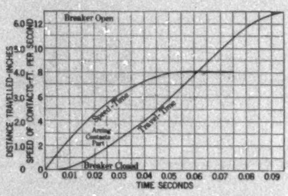

FIG. 4—SPEED OF TRAVEL CURVES OF THREE-POLE SINGLE-THROW BREAKER IN ONE ROUND TANK

The type of design shown in Figs. 1 and 2, after extensive factory and field tests on the 20-in. tank size, gave promise of extension to other capacities; and a line of circuit breakers comprising four tank sizes is shown in Fig. 3, with ratings as follows:

| Inside diameter of tank | Amperes at rated voltage | Approximate arc kv-a. |
|---|---|---|
| 16 in. | 7,500 at 7,500 volts | 100,000 |
| 20 " | 5,000 at 15,000 " | 130,000 |
| 26 " | 8,000 at 15,000 " | 200,000 |
| 32 " | 14,000 at 15,000 " | 350,000 |

The performance of a breaker depends upon two principal factors. The first of these is the amount of energy released in the structure when opening short circuits, which may be called the energy, or duty factor. The second is the ability of the structure provided to take care of this energy after it has been formed, which might be called the structure factor. The energy factor is represented by the integrated kilowatt-seconds obtained from the short-circuit current oscillograph record and the arc-voltage oscillograph record. The relationship of arc energy to short circuit kv-a. varies greatly with different designs of circuit breaker and also with different conditions of operation on the same circuit breaker structure.

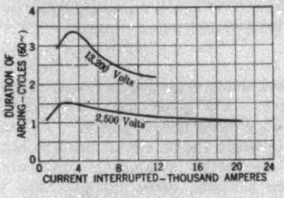

FIG. 5—CURVES SHOWING DURATION OF ARCING WITH CURRENT INTERRUPTED AT DIFFERENT VOLTAGES

A high-voltage circuit breaker handling small currents on short circuits has an entirely different ratio of arc energy to short circuit kv-a., than that of a low-voltage breaker handling high currents on short circuits. Likewise a breaker designed for, say, 15,000 volts will have a different ratio when operated at 2500 volts. A knowledge of the variations of arc energy with short circuit kv-a. is necessary to the successful design of a line of circuit breakers. This is especially so because facilities for testing the largest breakers do not exist and their design depends on extrapolating results obtained on smaller sizes.

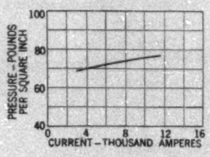

FIG. 6—TANK PRESSURE VARIATION WITH CURRENT INTERRUPTED ON THREE-PHASE, 60-CYCLE, 13,200-VOLT UNGROUNDED SHORT CIRCUITS. THREE-POLE BREAKER IN ONE ROUND TANK

Figs. 5 to 14, inclusive, show various operating characteristics of the multiple breaker in a common round tank when opening three-phase short circuits on a 60-cycle, ungrounded neutral system.

In Fig. 5 is shown the relationship between short circuit amperes and cycles of arcing at 13,200 volts and 2500 volts for a given breaker structure of the type under discussion. This is simply a curve of averages and is subject to considerable variation between successive short circuits. It serves, however, to indicate the general relationship between duration of an arc and the amount of current in the arc. The shape of this curve is affected by speed of parting of the contacts, the number of breaks in series per phase, the magnetic blow-out effect of the current-carrying loop, the spacing between the arcing contacts and the tank liners, and to some extent on the head of oil over the contacts and the volume of the air-chamber. From the point of view of the system connected to the breaker, the shape of this curve depends on the restored voltage, whether the neutral is grounded at the short circuit as well as at the machine, the power factor during the short circuit, and other considerations.

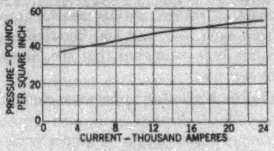

Fig. 7—Curve Similar to that in Fig. 6, for 2500-Volt Service

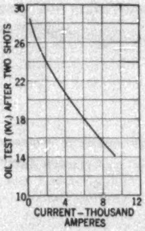

Fig. 8—Oil Test—Three-Pole Breaker in One Round Tank after Opening Three-Phase, 60-Cycle, 13,200-Volt Ungrounded Short Circuits

It has been found, however, that for 15,000 volts (and below, especially) curves of the general shape shown in Fig. 5 are secured under different conditions of system and breaker characteristics.

In Fig. 5 it is noticeable that the time of arcing for large currents is less than that with relatively small currents. The arcing time increases for a while with current, but there comes a point where this time begins to diminish rapidly, and finally the curve becomes practically asymptotic. The position of the high part of this curve depends on the magnetic blow-out action on the arcs. The type of breaker shown keeps the high point of the curve at lower current values than do some other types, because the current-carrying loops are closer together and the magnetic blow-out effects, in general, are greater. It will be obvious that a lower time of arcing at high currents results in a reduction in the arc energy dissipated in the breaker and resulting oil throw, contact depreciation, and stresses which the structure has to withstand.

Curves in Fig. 13, showing single-phase arc energy as a function of current interrupted, are of interest. For the particular case, the arc energy varies almost directly as the short circuit current but differs greatly for the different voltage classes. This is readily seen from the differences in arcing times shown in Fig. 5.

An interesting relationship is that between kilowatt-seconds dissipated in a breaker and the kv-a. of the short circuit interrupted by it. From Fig. 13 we find that for 13,200 volts the three-phase kilowatt-seconds of arc energy is 0.0035 of the three-phase short-circuit kv-a. As an illustration: at 6000 amperes the arc energy for 13,200 volts is 160 kilowatt-seconds per phase.

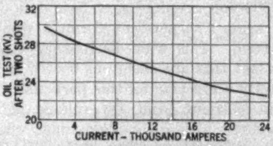

Fig. 9—Curve Similar to Fig. 8, Except for 2500-Volt Circuits

$$\text{The relation } \frac{\text{Arc energy in kilowatt-seconds}}{\text{Kv-a. interrupted}}$$

$$= \frac{3 \times 160}{13.2 \times 6000 \times \sqrt{3}} = 0.0035$$

In the same way, for 2500 volts the ratio is 0.0049. Accordingly, there is more energy lost per kv-a., in a breaker of this particular design, on low voltage, such as 2500 volts, than on 13,200 volts. With other designs of breaker this relationship may not hold, and the factors of arc energy related to kv-a. in the short may be quite different.

Several articles have been written on this general matter and it is interesting to note comparable results. Mr. P. Charpentier in the *Rev. Gén. Elec.*, May 14, 1921, developed a formula for arc energy in terms of circuit voltage, short-circuit current, and time of arcing in which he assumed that time of arcing varied directly with voltage for a given velocity of contacts. According to Charpentier's formula a breaker of this design opening 6000 amperes, three phases on a 13,200-volt circuit would have a factor of 0.0031 as the relationship between arc energy and short-circuit kv-a. This is in close agreement with the similar factor derived from the data here presented.

However, for short circuits of similar kv-a., on lower voltages this agreement does not hold. The average ratio for 2500-volt circuits (taken from data on Fig. 13) is 0.0049, while Charpentier's formula would give a ratio of 0.0006. This wide discrepancy is accounted for by the fact that arc energy as shown in Fig. 13 is rather directly a function for this particular breaker of short-circuit currents, and arc voltage at the high currents secured with low-voltage short circuits is a considerably greater proportion of line voltage than it is for higher voltage circuits. This is borne out by Figs. 10 and 11. From Fig. 10 we find that for 13,200 volts the average arc voltage at 6000 amperes is approximately 8 to 9 per cent of phase voltage, whereas for similar kv-a. at 2500 volts the average arc voltage is approximately 25 to 30 per cent, as indicated by Fig. 11.

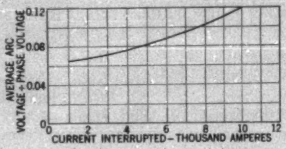

Fig. 10—Variation of Average Arc Voltage to Phase Voltage Ratio with Respect to Current Interrupted, 13,200-Volt, 60-Cycle Ungrounded Circuits

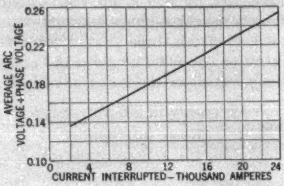

Fig. 11—Curve Similar to Fig. 10, Except for 2500-Volt Circuits

In the development of the line of breakers shown in Fig. 2 an unusual amount of short-circuit testing has been possible. In 1923 the Detroit Edison Company cooperated in the development and testing of the 20 in. tank size. At their Delray Station currents as high as 25,000 amperes at 4800 volts were handled successfully, and with much less signs of stress on the structure than on conventional forms of breakers of larger physical size. Afterward a 40,000-kv-a., 10-per cent reactance factory test plant became available, and exhaustive series of tests have been made.

It has not been possible to destroy or seriously damage the 20-in. size on the 40,000-kv-a. test set. The ability of the larger sizes, therefore, for the present must remain a matter of extrapolation. We know that the general characteristics of a small size for available test conditions is as shown in Fig. 13. The larger sizes can be tested, of course, within present power limitations. From such test data and knowledge of general characteristics it is estimated that the larger sizes are conservatively rated.

The intimate relationships between current carrying loops in this type of breaker involved recourse to certain special design features. On currents of 40,000 to 50,000 amperes it was found that ordinary, porcelain terminals would shatter under the blows imposed upon them by the reaction of the loops. It was necessary to use a terminal insulation, having mechanical strength and at the same time sufficient flexibility to prevent breakage. The condenser type terminals with heavy ground band and clamp construction, as shown in the illustrations, seemed most desirable.

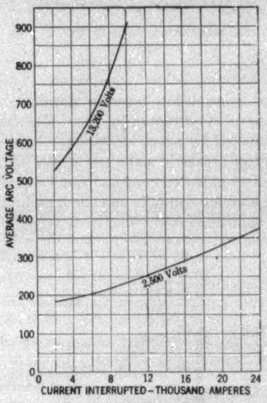

Fig. 12—Relation of Average Arc Voltage to Current Interrupted for Three-Phase, 60-Cycle Ungrounded Short Circuits. Three-Pole Breaker in One Round Tank

A similar mechanical action took place between the moving contacts at high currents. During one test made, with current rushes of 60,000 to 70,000 amperes at 4800 volts on the 20-in. tank size, the circuit was ruptured not by the opening of the breaker in the ordinary way, but by the fracture of the lifting rods causing the moving contacts to be thrown violently into the bottom of the tank. The circuit was ruptured with approximately one-half cycle of arcing on 60 cycles and represents one more of those cases where the operation was successful but the patient died. It was found desirable to strap the moving contact elements together where heavy currents at the lower voltages were involved.

The question frequently is asked whether the mechanical speed of operation of a breaker is seriously affected by the short-circuit current flowing through it. Mechanical strains on contact parts due to mechanical blow-out effects are a function of the square of the current. Fig. 14 shows the speed of operation of a breaker such as referred to with varying currents being interrupted. The general conclusion may be drawn that for small structures having close mechanical loops this effect becomes noticeable around 15,000 amperes and increases in effect fairly rapidly with current increase beyond that point.

There are certain diversity factors about this type of breaker that will interest an operating man. The oil volume and air volume are common to the three poles. Since by far the greater number of short circuits is single phase, the total oil volume will not depreciate as fast as though the single-phase short circuit had been on one-third of the oil, which would be the case with a multipole breaker having separate tanks. Also, the common air volume tends to diminish the shock to the breaker structure that occurs on single-phase short circuits, so that while the maximum pressure to which the breaker may be subjected may be considerable, yet the average pressure under operating conditions will be reduced. In general, it is felt that less maintenance for a given duty will be obtained with this form of breaker than with a multiple, single-pole breaker, and also that the maintenance is more easily and quickly performed.

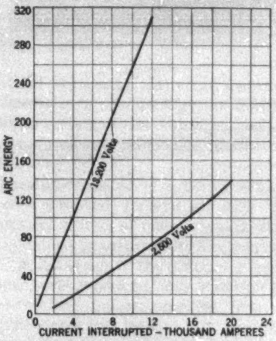

FIG. 13—RELATION OF ARC ENERGY PER PHASE TO CURRENT INTERRUPTED ON 60-CYCLE UNGROUNDED CIRCUITS. THREE-POLE BREAKER IN ONE ROUND TANK

A careful analysis of test data is necessary in formulating ratings. Actual operating conditions vary from test conditions. Over the life of a breaker operating speed may vary somewhat, the condition of the oil will change at times, and certain circuit conditions will be found much harder on a breaker than others. With a general understanding of the operating characteristics of a breaker, test data can be properly evaluated and a rating given that will be conservative and insure satisfactory operation.

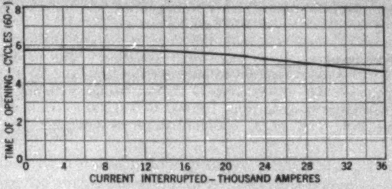

FIG. 14—RELATION OF TIME OF OPENING FROM BEGINNING OF MOVEMENT UNTIL COMPLETION OF STROKE AGAINST CURRENT INTERRUPTED. THREE-POLE BREAKER IN ONE ROUND TANK

---

## Discussion

**R. R. McGee:** As Mr. MacNeill has brought out, oil circuit breakers of minimum size for moderate interrupting capacity and moderate voltage are constantly assuming greater importance. Operators are demanding breakers which are safe and reliable, and which will occupy the minimum of space and require the minimum of maintenance attention.

As a result of this increasing demand the writer's company has applied to a new round-tank breaker many of the electrical and mechanical principles of design essential to the larger breakers.

Among the design features essential to the attainment of high interrupting capacities are: the internal unit mechanism, oil-separating chambers and gas vents, round tanks with dome covers, and ample mechanical strength. All of these features are to be found in the new round-tank breaker for moderate interrupting capacity. The internal mechanism, of course, prevents contact reclosure due to unbalanced pressures acting on the mechanism; the separating chambers and gas vents provide adequate relief for the gases without permitting oil throw; and by proper design of the round tank with its dome cover ample mechanical strength is secured.

The moderate-duty breaker employs one tank for all three phases with considerable saving of space.

The top frames are dome-shaped because this construction, together with the use of a round tank, eliminates distortion. The heavy, bulky, and expensive castings formerly used have been replaced by the lighter but stronger boiler-plate construction.

The contacts of this new moderate-capacity breaker are of the wedge-and-finger construction. The stationary contact fingers are the so-called wide-angle fingers. They are self-alining, and their contact surfaces are at all times maintained parallel to the contact surfaces of the blade, thus assuring maximum contact. Extended fingers and a removable section of the blade are used to bear the brunt of the arcing, protecting the main contact surfaces. Contacts of this same type are employed in the plain-break breakers of larger size and are also used in many cases to supplement the explosion-chamber contacts.

There is a little similarity however, between the bushings which support the contacts. In the smaller breaker, designed only for moderate voltages and for indoor service, bushings of Herkolite surround the central conductor. The assembled bushings are individually removable from the frame. In the larger breakers where higher voltages are encountered, compound- or oil-filled porcelain bushings are used.

Of course there is a wide difference in the application of the several breakers which have been described. The moderate-capacity breakers referred to are built for 7500- and for 15,000-volt service, 400- to 3000-ampere current ratings, with interrupting capacities ranging from 100,000 to 250,000 kv-a., in accordance with N. E. M. A. standard steps, as determined by the selection of a 16-in. to 32-in. tank. The new line of large indoor oil circuit breakers has voltage ratings of 15,000, 25,000, or 37,000 volts, with normal currents up to 4000 amperes. Here the interrupting capacities vary from 350,000 to 2,000,000 kv-a., with tanks ranging from 16 in. to 36 in. in diameter. The round-tank breakers for outdoor service are built for all standard voltages from 15,000 to 220,000 volts, and may be obtained with either finger-and-wedge, or explosion-chamber contacts, except above 154,000 volts where explosion chambers only are used. Interrupting capacities from 350,000 to 750,000 kv-a. can be obtained from the plain-break breakers. When explosion chambers are used, interrupting capacities from 750,000 to 2,500,000 kv-a. are available. The tanks are mounted directly on the foundation for higher voltages, and with this mounting manholes are provided to afford inspection of the internal parts.

# The Vibration of Transmission-Line Conductors

BY THEODORE VARNEY[1]

Associate, A. I. E. E.

*Synopsis.—This paper is a continuation of a former one by the writer in May, 1926.*

*Records are given of vibration in actual transmission lines under widely varying conditions and with various conductor materials. These observations indicate the limiting values of wavelength frequency and amplitude of such vibrations encountered in service.*

*Laboratory experiments are described in which the observed conditions were artificially reproduced in a large conductor. The stresses adjacent to a point of support were studied with the aid of a microscope. The wave shape was plotted and the energy required to maintain vibration was recorded.*

*All conductor vibration breaks observed in practise have occurred at supports or badly made joints. The conclusion is reached that if the radius of curvature at the support can be maintained at least equal to that at the center of a loop, no breakage will occur.*

*Mathematical expressions are given for determining the radius of curvature at the center of a loop, the bending moment at a support, and the necessary additional amount of conductor stiffness at the support to satisfy the desired condition.*

*A simple form of stiffening device is described which even in a more crude form has been found effective in several cases of actual service.*

---

IN the previous paper[2] the writer discussed the action of the wind on a suspended conductor and gave rules for determining the wavelength and frequency of the resulting vibrations.

Since the date of that paper, records have been kept of the wind action upon a large number of transmission lines equipped with different kinds of conductors and installed under various conditions. Typical cases selected from these data are listed in Table I.

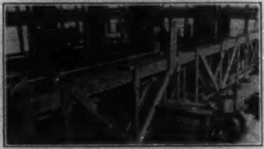

FIG. 1—FRAME FOR TESTING VIBRATION OF CONDUCTOR

Experimental apparatus was next installed at the Carnegie Institute of Technology at Pittsburgh by means of which certain of the data observed in the field could be reproduced in a particular conductor of large size.

This apparatus consisted of a heavy wooden frame provided with grooved pulleys at each end. The distance between centers of pulleys was 50 ft. and tension was maintained by turnbuckles and a dynamometer installed in the lower side of the conductor loop.

Vibrations were produced and maintained by an 1/8-hp., 110-volt d-c. motor, operated from a storage battery. The motor was located 6 ft. from one end of the span and was belted to a small counter shaft carrying a flywheel, a tachometer, and a crank disk. The latter was arranged to receive a wrist pin at varying radii, and which in turn engaged with a light wooden connecting rod and guided plunger. This plunger was connected with the conductor by means of a small spiral tension spring. The travel of the plunger was adjusted to 1½ in. when the spring tension varied from ¾ to 4 lb.

The field of the motor was separately excited and held constant. The armature speed was controlled by an adjustable resistance. The power consumed was so small that the speed of the motor could be held constant and the conductor maintained in resonant vibration continuously. By varying the speed, one, two, three, and four loops could be obtained.

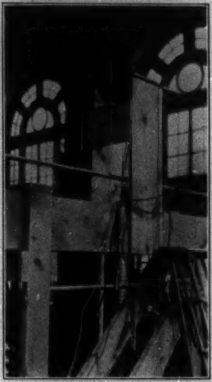

FIG. 2—SHOWING METHOD OF VIBRATING CONDUCTOR

Table II gives conductor tension, loop length, amplitude, frequency, and watts input to motor when vibrating the conductor and when disconnected. The power consumption is inconsistent as will be noted by the fact that in some cases it is less when connected than when disconnected. This is believed to indicate that the friction losses were variable and large compared to the

S. C. = Stranded Copper.
S. S. = Stranded Steel.

energy consumption of the vibrating conductor. The small power required is noteworthy in view of the fact that the conductor in this case was 1.093 in. diameter, weighed 1.024 lb. per ft., and in some cases was under a tension of 9000 lb.

In order to obtain definite conditions at the point of support, a heavy cast-iron block was bolted to the framework near one of the pulleys. This block held a split steel bushing bored out to fit the conductor accurately and tightly. The distance from the end of this bushing to the center of the other pulley was exactly 48 ft.

A high power microscope was bolted to this block so that no relative motion between them existed. The microscope was then focused on the top of the conductor next to the end of the bushing. By means of an eyepiece micrometer the maximum longitudinal motion of a point on the top strand of the conductor was observed to be approximately 0.000656 in. with a tension of 9000 lb. The path of the observed point diminished longitudinally as the microscope was rotated from the top toward the side of the conductor, becoming more and more oblique and approaching a right angle with the longitudinal axis of the conductor on the horizontal transverse diameter. This last condition was due to the transverse motion of vibration and indicates that the strand fibres on the side are not subjected to pulsating longitudinal stresses as are those on the top and bottom of the conductor. No effect of longitudinal vibratory impact could be discerned and the effects noted above are undoubtedly due to simple transverse bending in the vertical plane. The transverse motions of the conductor were carefully noted and plotted. The resulting curves are sine waves for all loops not adjacent to a support. The supports distort the wave, producing a bending action adjacent to it and a point of inflexion in the first half of the loop.

FIG. 3—CAST-IRON BLOCK ON TEST FRAME

In all of the cases recorded in Table I, no breakage of strands has occurred except adjacent to a support or at a joint which had been either poorly designed or applied. It is a logical conclusion that if means can be found to prevent any sharper bending of the conductor at a support or at a joint, than occurs at the middle point of a loop, breakage due to vibration will be prevented.

Considerable thought and ingenuity have been expended upon the design of suspension clamps, but so far as the writer is aware no logical method has previously been developed to determine the proper shape of the conductor seat. The support cannot be regarded as a simple node and it is difficult to provide effective means for permitting the wave to pass through the suspension clamp without bending the conductor. The reason for this is that it is impossible always to have a wave impulse leaving on one side of a support at the instant it is arriving on the other. This is evidenced by recorded cases of broken strands while the conductor rested on a sheave.

TABLE II.

| 7500 | 12 | 20. | 19.13 | 46.87 | 48.30 |
| 9000 | 48 | 102. | 5.33 | 10.73 | 8.80 |
| 9000 | 24 | 18. | 10.60 | 21.70 | 21.30 |
| 9000 | 16 | 16. | 15.67 | 34.20 | 36.50 |
| 9000 | 12 | 12. | 20.87 | 52.20 | 54.40 |

If the suspension clamp could be designed with a radius as large as that at the loop center it would be effective but it is difficult to do this within available limits of design. The angle of the conductor with the horizontal in a span of the greatest practicable length and sag at present in use, or contemplated, is about 23 deg. The summer to winter variation would be on the order of 2 deg. or 3 deg. while the vibration angle is less than ½ deg. The correcting means must therefore be applied to the moving conductor.

A simple and practical method is to apply to the conductor a layer of cylindrical rods at the support. Preferably each rod tapers at each end, thereby enabling it to be twisted around the conductor and held at the ends. This gives maximum resistance to bending at the support and a tapering mass on each side to prevent sudden reflection of waves at its ends. This arrangement is illustrated in Fig. 4.

The above conclusions are based upon the observations and experiments described and also upon the following theory. Referring to Figs. 5 and 6, the letters have the following meanings:

$L$ = Loop length = half wavelength
$A$ = Amplitude of complete vibration
$R$ = Radius of curvature at middle point of loop
$Q$ = Angle with axis at node point of freely vibrating loop
$F$ = Frequency of vibration in cycles per sec.
$V$ = Velocity of transverse wave in ft. per sec.
$P$ = Total tension in conductor in lb. (conductor not vibrating)
$l$ = Arc-length of loop

$W$ = Weight per ft. of conductor in lb.
$G$ = Acceleration due to gravity = 32.2 ft. per sec.
$K$ = Moment producing bending at support
$I$ = Moment of inertia of complete cable and damper at support
$I_s$ = Moment of inertia of steel-core of conductor
$I_a$ = Moment of inertia of aluminum part of conductor
$I_d$ = Moment of inertia of damper at support
$M$ = Virtual modulus of elasticity of complete conductor and damper
$M_s$ = Modulus of elasticity of steel
$M_a$ = Modulus of elasticity of aluminum
$M_d$ = Modulus of elasticity of damper material

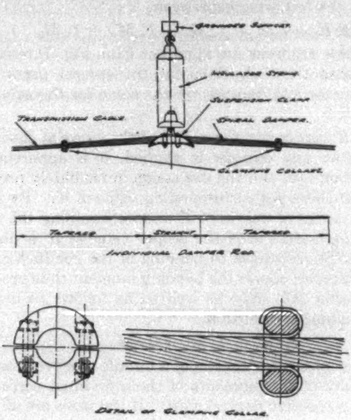

FIG. 4

$$V = \sqrt{\frac{P_e}{W}} = 2\,L\,F \qquad (1)$$

$$y = \frac{A}{2}\sin\theta = \frac{A}{2}\sin\frac{\pi\,x}{L} \qquad (2)$$

$$\tan Q = \frac{dy}{dx} = \frac{\pi\,A}{2\,L}\cos\frac{\pi\,x}{L} \qquad (3)$$

$$= \frac{\pi\,A}{2\,L} \text{ at origin when } x = 0$$

$$d\,l = \left[1 + \left(\frac{dy}{dx}\right)^2\right]^{1/2} dx \qquad (4)$$

$$\left(\frac{dy}{dx}\right)^2 = \frac{\pi^2\,a^2}{L^2}\cos^2\frac{\pi\,x}{L}$$

$$= \frac{\pi\ a^2}{l^2}\left(1 - \sin^2\frac{\pi\,x}{L}\right) \text{ when } a = \frac{A}{2}$$

$$d\,l = \sqrt{\frac{L^2 + \pi^2\,a^2}{L^2} - \frac{\pi^2\,a^2}{L^2}\sin^2\frac{\pi\,x}{L}}\,dx$$

$$\frac{\pi\,x}{L} = \theta,\quad x = \frac{L\,\theta}{\pi},\quad dx = \frac{L}{\pi}\,d\,\theta$$

$$d\,l = \frac{L}{\pi}\sqrt{\frac{L^2 + \pi^2\,a^2}{L^2} - \frac{\pi^2\,a^2}{L^2}\sin^2\theta\,d\,\theta}$$

$$= \frac{\sqrt{L^2 + \pi^2\,a^2}}{\pi}\sqrt{1 - \frac{\pi^2\,a^2}{L^2 + \pi^2\,a^2}\sin^2\theta\,d\,\theta}$$

$$l = \frac{2\sqrt{L^2 + \pi^2\,a^2}}{\pi}\int_0^{\frac{\pi}{2}}\sqrt{1 - \frac{\pi^2\,a^2}{L^2 + \pi^2\,a^2}\sin^2\theta\,d\,\theta}$$

This expression can be integrated approximately as follows:—

$$l = L\sqrt{1 + \frac{\pi^2\,a^2}{L^2}}\left[1 - \frac{1}{4}\,\frac{\pi^2\,a^2}{L^2\left(1 + \frac{\pi^2\,a^2}{L^2}\right)}\right.$$

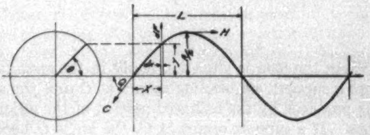

FIG. 5

$$\left. - \frac{3}{64}\,\frac{\pi^4\,a^4}{L^4\left(1 + \frac{\pi^2\,a^2}{L^2}\right)^2} - \frac{5}{256}\,\frac{\pi^6\,a^6}{L^6\left(1 + \frac{\pi^2\,a^2}{L^2}\right)^3}\right]$$

put

$$m = \frac{\pi^2\,a^2}{L^2} \text{ and } \sqrt{1 + m} = 1 + \frac{1}{2}\,m - \frac{1}{8}\,m^2 + \frac{1}{64}\,m^3;$$

consolidating:

$$l = L\left(1 + \frac{1}{4}\,m - \frac{3}{64}\,m^2 + \frac{5}{256}\,m^3\right)$$

$$l = L\left(1 + \frac{1}{4}\tan^2 Q - \frac{3}{64}\tan^4 Q + \frac{5}{256}\tan^6 Q\right) \qquad (5)$$

Since for any case of vibration recorded $Q$ is very small (not over approximately ½ deg.) tan $Q$ is small and $l$ is so little greater than $L$ that the tension $P$ may be taken constant. This is the fundamental assumption upon which equation (1) is based.

$$R = \frac{\left[1 + \left(\frac{dy}{dx}\right)^2\right]^{3/2}}{\frac{d^2 y}{d x^2}}$$

$$= \frac{\left[1 + \left(\frac{\pi A}{2 L} \cos \frac{\pi x}{L}\right)^2\right]^{3/2}}{\frac{\pi^2 A}{2 L^2}\left(- \sin \frac{\pi x}{2}\right)} \qquad (6)$$

$$= \frac{2 L^2}{\pi^2 A} = \left(\frac{1}{\tan Q}\right)\left(\frac{L}{\pi}\right) \text{ when } x = \frac{L}{2} \qquad (7)$$

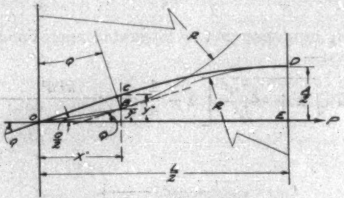

FIG. 6

When the loop is vibrating freely in the span, away from a support, no bending occurs at *O* and the angle *Q* is produced by the balanced motion of the adjoining loops. If a support occurs at *O*, the angle *Q* becomes zero at the left of *O* and the conductor is alternately bent up and down through the angle *Q*. Although the angle *Q* is small, the bending produces very considerable fiber stresses which added to the direct tension in the cable has produced breakage.

In Fig. 6, a circle of radius *R* is drawn tangent to the axis of *X* at the origin *O*. At a point *B* a tangent is drawn to this circle parallel to *O C*. This tangent makes an angle *Q* with the axis of *X*. The arc *O B* subtends an angle at the center equal to *Q* and the angle

$B\,O\,E$ equals $\frac{Q}{2}$.

The arc length *O B* is obtained as follows:

$$\text{Arc } O\,B = \frac{Q}{360}\, 2\,\pi\,R$$

Chord *O B* = arc *O B*, very nearly, since *Q* is small.

$$y' = O\,B \sin \frac{Q}{2} \qquad (8)$$

Since *Q* is small *X* may be taken equal to *O B* and substituting this value of *X* in equation (**2**):

$$y'' = \frac{a}{2} \sin \frac{\pi X'}{L} \qquad (9)$$

When the loop is freely vibrating the tension in the wire produces no bending at *O*. When bending occurs at *O* the resultant of the tension in the cable does not pass through *O* and the bending moment is the product of the tension and the offset of the bend.

Under the conditions indicated in the figure the bending moment at *O* is represented as follows:

$$K = P\,.\,B\,C = P\,(Y'' - Y'), \text{ very nearly.} \qquad (10)$$

In order to satisfy these conditions the following relation must obtain:

$$I\,M = R\,K \qquad (11)$$

In order to satisfy this condition, *I* must usually be greater than the value corresponding to the wire itself. This value may be obtained by a reinforcing wrapping or damper, the proportions of which may be determined from the following expression.

$$R\,K = I\,M = I_s\,M_s + I_a\,M_a + I_d\,M_d \qquad (12)$$

These relations are apparent from Fig. 7, remembering that the deflections for the several parts of the conductor and damper are the same for the same lever arm *h*.

If *R'* represents the radius of the curve at the right of 0 before any damper is applied, it is apparent from equation (**10**) and the discussion immediately preceding it that there is a corresponding value of *K*. By assuming a series of values of *R* and determining the corresponding values of *K* the proper value of *R'* is obtained when the resistance to bending of the conductor, without damper, equals the bending moment thus produced. Equation (**12**) may be written as follows to illustrate this balanced condition:

$$R'\,K' = I_s\,M_s + I_a\,M_a \qquad (13)$$

The moment of inertia of a bundle of wires is equal to the sum of the moments of the individual wires about their respective neutral axes. If the wires are all under tension and parallel the moment of inertia of the bundle may be taken as the sum of the moments of the individual wires about the neutral axis of the bundle.

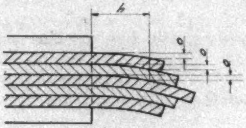

FIG. 7

In a conductor the wires are usually arranged in a spiral, which tends to equalize the stresses due to bending. On the other hand friction between the wires tends to counteract this effect.

Referring to Fig. 8 and first assuming the case at the middle of a loop, the individual strands are only restrained from slipping lengthwise with respect to one another by the friction between them produced by the conductor tension. Examining the behavior of an individual strand in the outside layer and denoting tension stress by the sign (+) and compression stresses by the sign (−), the part of the strand outside of the neutral axis of the complete conductor is (+) and the part inside is (−). At the crossing of the neutral axis the stress due to bending is zero. The small arrows indicate the direction in which the material of the strand tends to flow under the action of these stresses.

The adjacent strands of the same layer are moving almost synchronously with respect to each other. This is not the case, however, between the strands of adjacent layers and particularly where they cross each other at the neutral axis. In Fig. 8 the arrows indicate that while the outer strand tends to move toward the left the inner strand is trying to move toward the right.

If the strands of the successive layers were spiralled in the same direction much of this tendency would be removed. Steel cables designed to travel over sheaves are usually made this way and in a few cases of long river crossings the steel cores of A. C. S. R. have been so specified. However, the reversed lay construction is almost universally used for transmission conductors and so far as the writer is aware no conductor failure has been identified with this cause.

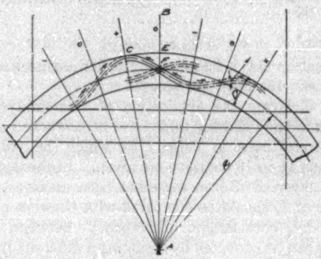

FIG. 8

If the strands are not restrained by friction, the fiber stress in each strand is due only to bending about its own neutral axis. Thus:

$$J_{Md} = \text{Max. Fiber Stress} = M_a \frac{d}{2R} \qquad (\mathbf{14})$$

If the friction between the strands were increased by any means so that all relative slipping ceased, then the maximum fiber stress would be expressed as follows:

$$J_{MD} = \text{Max. Fiber Stress} = M_a \frac{D}{2R} \qquad (\mathbf{15})$$

The true value of the fiber stress is somewhere between these extremes and is close to that given by equation (**14**).

Suppose now that a supporting clamp is applied to the conductor in such manner that all of the strands to the right of the line *A B*, Fig. 8, are prevented from slipping. The flow in the strand shown in Fig. 8 will no longer be equalized at *C* and a longitudinal stress approaching the value given by equation (**15**) will result. The strand which crosses line *A B* at *E* will not thus be affected and its stress will be represented by equation (**14**). Other strands have intermediate values of stress.

Referring to equation (**13**) the values of $I_s$ and $I_a$ will depend upon whether the neutral axis is taken at the center of the conductor or at the center of each strand. Similarly, the value of $R'$ will depend upon this same condition. The rather interesting fact develops that the fiber stress in the undamped conductor at the support is practically the same no matter which of these assumptions is made.

Table III represents one of the sets of observations given in Table I. The column headed $J_d'$ represents the fiber stress in the conductor at a support with neutral axis at center of each strand. $J_D'$ is the corresponding value with axis at center of conductor. Throughout this list these values are practically equal.

Table III further illustrates the effect of a damper cage consisting of seven aluminum rods each 0.475 inch diameter. In this case the radius of curvature is represented by $R_d''$, the fiber stress in the aluminum part of the conductor is given by $J_d''$ and the stress in the damper rods by $J_d'''$.

In this case the bending moments and stresses are based on the assumption that the neutral axis is at the center of the individual members of the entire conductor and damper.

In Table III the last two cases are hypothetical as regards loop length and amplitude for − 20° fahr. All the others are observed.

In the following nomenclature the subscripts *O*, 1, 2, 3, 4, 5, 6 refer respectively to the central wire and the successive layers of the conductor and damper from the center outward. The small letters $i_0$, $i_1$, etc., refer to the moments of inertia of the individual wires of the several layers. The large letters $I_0$, $I_1$, etc., refer to the moments of inertia of corresponding layers. The small letters $n_1$, $n_2$, etc., refer to the number of wires in each layer. The small letters $d_0$, $d_1$, $d_2$, etc., are the diameters of individual wires of the respective layers. The letters $M_0$, $M_1$, etc., refer to the respective moduli of elasticity of the materials forming the respective layers. $D_0$, $D_1$, $D_2$, etc., refer to the diameters of the circles circumscribing the respective layers.

Referring to Fig. 9:

$$d_0 = D_0$$

$$d_1 = D_0 \left( \frac{\sin \theta_1}{1 - \sin \theta_1} \right) \text{ when } \theta_1 = \frac{360}{2\, n_1}$$

| 1020 | −20 | 2720 | 14.0 | 10. | 12.2 | .002921 | 1525 | 52 | 56 | 1416 | 173 | 1370 | 313 | 253 | 570 |

$$d_2 = D_1 \left( \frac{\sin\, \theta_2}{1 - \operatorname{Sin}\, \theta_2} \right) \text{when } \theta_2 = \frac{360}{2\, n_2}$$

$$d_6 = D_5 \left( \frac{\sin\, \theta_6}{1 - \operatorname{Sin}\, \theta_6} \right) \text{when } \theta_6 = \frac{360}{2\, n_6}$$

$$I_0 = i_0 = \frac{\pi}{64}\, d_0^4$$

Assuming the neutral axes at the center of each strand:

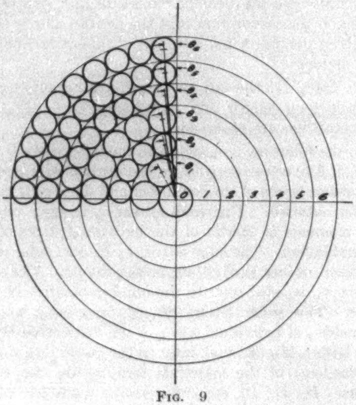

FIG. 9

$$I_1 = \frac{n_1\, \pi\, d_1^4}{64}$$

$$I_2 = \frac{n_2\, \pi\, d_2^4}{64}$$

$I_c$ = Total moment of inertia = $I_1 + I_2$ etc.

Assuming the neutral axis at the center of the cable:

$$I_1 = \frac{\pi}{64}\, n_1\, d_1^4 + \frac{\pi}{16}\, d_1^2\, (D_0 + d_1)^2$$

$$[R^4 \cos^2 \theta_1 + \cos^2 3\, \theta_1 + \ .\ .\ .\ + \cos^2 (2\, n_1 - 1)\, \theta_1]$$

Equation (**14**) is based upon the first assumption and equation (**15**) upon the second.

To illustrate the application of this analysis the values in the following table have been worked out for the several cases in Table I for which the values in columns 11 to 19 inclusive are given. In these cases a single layer of 12 iron wires has been assumed. The values of $I_d$ should be compared with those in column 19. Any considerable discrepancy between these values can be corrected by assuming a different number of wires for the damper. Also considerable variation is possible when different materials for the damper wires are used.

| Diam. of cylindrical part of damper wires. (In.) | Values of $I_d$ |
|---|---|
| 0.4153 | 0.578,253 |
| 0.3643 | 0.342,379 |
| 0.3333 | 0.239,959 |
| 0.3013 | 0.160,253 |
| 0.2413 | 0.065,928 |

Equation (**15**) was used in the above analysis.

The effect of the damper is not only to increase the radius of the bend at the support but also to reduce the amplitude, frequency, and loop length which still further reduces the fiber stress due to bending.

It may be added that dampers similar to the type described herein have been in operation in certain cases for about three years, without breakage of conductor strands, whereas before the application of the dampers, breakages had occurred within from two to three months after installation.

In conclusion, the fact remains that in none of the cases recorded herein does the total normal tension stress plus the bending stress in the aluminum part of the conductor reach the endurance limit values which have as yet been established by the usual laboratory methods. The inference is that the bending action at the support creates an unequal distribution of the stresses between the several strands alternately overloading some of them and relieving others. If this bending can be sufficiently restricted, the damaging results must disappear.

The problem has been approached in a different manner by Mr. G. H. Stockbridge, Engineer of Transmission, Southern California Edison Co. He has successfully suppressed vibrations by means of an ingenious device located in the span some distance from the support.

The writer is indebted for valuable assistance to Prof. William R. Work, and Mr. F. E. J. Litot, Carnegie Institute of Technology. Also to Messrs. L. W. Henry, M. E. Noyes, H. H. Rodee, L. H. Hemeter, L. D. Hutcheson, R. L. Templin, and G. W. Stickley, Aluminum Company of America.

## Discussion

**D. D. Clarke:** Mr. Varney's paper has been of very great interest to me, because he depicts a problem with which I have come in contact.

One item of vibration that he mentioned deserves more attention. When the span is divided into several of these vibration loops, the loops seem to travel from one end of the span to the other and back again. In these cases, such rough and crude measurements as we have made indicate that there was a change in the tension, longitudinally, of the wire. This would not amount to a great percentage of the stress in the conductor.

This is the first item of research that I have noted that covers a definite procedure with regard to quantities involved, and leads directly to solving the reason for certain things happening in conductors, that we know do happen. Here is a very definite field for providing the proper devices to eliminate breakage troubles, due to the fatigue of conductors, even the fatigue of supports of the conductors.

In our experience with several thousand miles of this sort of wire in service, the breakage of the conductors at the point of support has been nil, but the breakages of supports have indicated the necessity of getting into the problem, and I have a very optimistic outlook, because of this research as demonstrated in the paper.

**J. B. MacNeill:** Considerable work has been done, the last two or three years, in connection with the measuring of stresses in railroad tracks, by actual recording devices of a sensitive nature. I was wondering if anything similar had been done here, or if an adaptation of those devices would eliminate some of the assumption it has been necessary to make. Personally, while I do not know much in detail about these devices, I think there would be considerable hope of help in that direction.

**Eli Ettlinger:** There is one particular phenomenon mentioned by Mr. Clark, that I think is of significant interest, and that is the question of the appearance of travel of the wave along the conductor. To me, that indicates directly the fundamental phenomenon which is taking place in the vibration of the conductor, which perhaps has been something of a mystery and still, perhaps, is fundamental.

The setting up of a steady state of vibration can fundamentally be broken down mathematically, and physically can be so demonstrated, into two decaying traveling waves in opposite directions. The original train of traveling waves in one direction and the reflected waves from the distant end, when superimposed, develop these standing waves.

Perhaps with the wind acting on the various portions of the suspended wire, the fundamental traveling wave is not of the same length as the reflected wave, and therefore the standing wave has the appearance of moving along.

When we undertake to analyze this vibration problem, I think it is well to get to the fundamental physical conception of the problem, before we attempt to tackle the mathematical analysis of it. Mr. Varney's first paper, some years ago, gave something of the conception of those fundamentals, attempting to set forth the manner in which these vibrations are set up by the wind. So far, we know of no other particular reason for the appearance of these vibrations. If we analyze these vibrations in terms of the traveling wave related to the fundamental velocity which a traveling wave may have, due to the tension and mass of the wire, as shown in Mr. Varney's first paper, then perhaps from that we can begin to get an analysis of what is occurring on a rigid support. However, when we get to a semi-flexible support and then perhaps to the flexible support, we have no definite manner of analyzing the problem.

As I understand it, Mr. Varney has made his mathematical attempt here on the assumption that the support is rigid, which is not directly true on our ordinary suspensions on transmission conductors. I have in mind, directly in connection with the analysis on the rigid support, a very recent opportunity to observe the breakage of wires. It happens to be a case to which most transmission men have neglected to give their attention in the past, and that is to overhead ground wires.

I speak specifically of a ground wire of high-strength steel, rigidly attached to wood poles. I have three samples of the broken wire. The attachment was perfectly rigid, there was no chance of flexibility, and the indications of vibration were quite obvious. The breaks occurred directly under the rigid support. The breaks were characteristic in that case, as Mr. Varney said, as being clean-cut and not drawn as if tension were the cause of the trouble.

I think that perhaps the radius, as indicated for bends which may take place at the rigid support, is a very important item. We have development by Mr. Varney now, which gives us some idea of the importance of that item, and a means of determining its magnitude.

In the cases of breakage mentioned the repair was made by attaching a parallel piece of cable with Crosby clips, which at the same time furnished the additional mass along the wire accomplishing the same thing Mr. Varney indicates.

The fundamental thought, given in many texts, of the traveling waves as taking place on ordinary wires and the like, may well be kept in mind in attacking the vibration problem.

The tension and the particular materials that are used in conductors requiring certain tensions to give certain sags, develop certain span lengths, would seem to be of vital importance. I mention specifically that the particular ground wire which was in trouble was of high-strength steel. The thought occurred to me that, perhaps, if the ordinary Siemens-Martin steel had been used in its place, our difficulties might not have been as pronounced.

The relationship of tension to mass is a direct function of the velocity of propagation of the traveling wave on a wire supported by rigid supports or otherwise. It is my thought that where that velocity of propagation is greatest, where the tension is highest, perhaps the bending is sharpest at a rigid support. It indicates something with relationship to the steepness of the wave front of the traveling wave; that steepness of wave front brings to mind the kind of radius which will develop at the support. I am inclined to reduce tensions where possible on conductors, in order to hold down that particular factor, which I term the velocity of propagation.

The stringing tension of that ground wire, using high-strength steel under maximum loading conditions, would have been of the order of 5000 lb.; using a 3/8-in. Siemens-Martin would have given satisfactory clearance in the same case, and would have held our tension down to 3000 lb. The relationship of veloctiy of propagation would have been reduced by the square root of those tensions.

In closing I would suggest to Mr. Varney that, perhaps, the fundamentals with relationship to the traveling wave, which must first be set up in order to get these standing waves, is probably of as vital importance in the study of this problem as the pure phenomena of the standing wave.

**Theodore Varney:** Replying first to Mr. MacNeill's question, I understand him to ask whether we have tried to carry on any accurate laboratory experiments whereby we measure the movements and stresses set up in the individual strands of the cable.

We must admit that our experimental work has lacked refinement. At the Carnegie Institute of Technology in Pittsburgh where we have been experimenting for the last year with the wooden frame and cable, we have not yet been able to work out any very accurate method of recording these experiments. As far as I can see, it will be difficult to obtain such records. We have tried to detect with a high-power microscope the actual movement of the particles of the cable but we could do this only in the outside strands.

The idea we had was, I think, similar to what Mr. Ettlinger suggests, *viz.*, the rather high velocity of a vibration or standing wave in a cable at pretty high tension conveys the thought of impact. That is what we tried to check with the microscope, but when we found we could not observe any longitudinal motion in the strands at the side of the cable, we came to the approximate conclusion that the stress effect was confined to bending.

Mr. N. B. Obbard, of the American Bridge Company, at Pittsburgh, once suggested to me the theory that the resulting wave in the conductor might be due to the combined effect of torsional, longitudinal, and transverse vibration.

The transverse wave predominates, but there is of course a very slight longitudinal varying stress which must set up a wave some 10 or 12 times higher in velocity than the transverse wave. There must also be present a slight amount of torsional vibration due to the spiral effect of the strands.

The point Mr. Obbard made was that if the period of the natural torsional vibration coincides with the eddy frequency of the wind, the transverse vibration would be amplified on the same principle as that used by Floettner in the rotating masts of his ship.

Since the longitudinal vibration might also have the effect of setting up transverse vibration, if of a proper frequency, Mr. Obbard thought all three might combine in some proper phase relation to account in some measure for the large amplitudes recorded in certain cases.

The speaker has no data to substantiate this theory and is rather of the opinion that the large amplitudes are explained by resonant conditions of the conductor with its system of supports together with a steady wind velocity acting uniformly over a considerable length of line.

I should like to add that this paper is not an attempt to go into deep mathematics. Mathematics have been introduced simply in the effort to explain observed effects. The theory of the radius of bending affords a simple explanation of what goes on in a conductor when it vibrates and further affords a simple remedy.

It is true if you add stiffness you will reduce the amplitude. Just how much is difficult to say without actual experiment, but just in proportion as the amplitude is reduced the vibration will be "damped." In other words, the damper scheme reduces the stresses to a safe point even if the amplitude were not reduced, but in addition to this if it reduces the amplitude we are still further on the side of safety.

It is true that the theory developed in this paper is based on the assumption of a rigid support which is not actually the case in any transmission line. It is believed, however, that whatever flexibility is provided by a well designed pivoted suspension clamp or other means is in the direction of additional safety. All that the writer has said as far as he can see, applies just as well under such conditions with probably improved results.

As to the question of tension in the cable, it is true that if tension is reduced the bending moment is reduced, provided the amplitude remains the same. Very often, however, when a cable is strung slack, "whipping" results. Whipping, as the speaker understands the term, is merely a low-frequency vibration of large amplitude. Such a vibration has been known to have very destructive effects. The type of damper described in this paper will tend to limit whipping.

The point is, if it is not necessary to string the conductor tight, don't do it; but if there is an economy to be gained, do not hesitate to do so. In either event, suitable safeguards against vibration or whipping should receive consideration in the construction of any transmission line.

# The Planning of Telephone Exchange Plants

BY W. B. STEPHENSON[1]
Non-member

***Synopsis.**—This paper discusses procedures followed in planning future extensions to telephone exchange plants to care for increased demand for telephone service. An outline is given of the methods employed in forecasting future demand for telephone service and in determining the most efficient design of the plant to meet the service requirements. The uses made of engineering comparisons in solving the economic phases of various kinds of telephone engineering problems are discussed, with particular reference to location and size or extent of major items of plant as well as the time when they should be ready to give service. Emphasis is placed upon the importance of those factors less readily evaluated, such as service factors, practicability from a construction and operating standpoint, flexibility, etc.*

* * * * *

TELEPHONE engineering involves many widely varying problems. Among these is the design of the various component parts of the telephone plant. This includes the design of central office buildings, the design of switching and power equipment to be housed in these buildings, the design of the trunk cable system with any loading necessary in order to connect these buildings, and the design of the distribution system. The distribution system includes, of course, the conduit, pole lines, feeder cable, distributing cable, house cable, etc., necessary to reach the subscriber's premises and connect his station equipment with the switching equipment in the central office.

Before the building can be designed in detail, however, determinations must be made as to whether the building should be built at all, where the building should be located, when it should be ready for occupancy, what area will be served by the building, and how much equipment must ultimately be housed in the building. Before the equipment for any particular building can be designed, we must know what type of equipment should be used and about how much business will be handled on this equipment. Before the trunk plant can be properly designed, we must know our future plans for increasing or decreasing the operating centers in a city, how much business will be handled on this trunk plant, and the economic allocation between transmission loss in the trunk plant and the transmission loss in the distribution plant. Before the distribution plant can be designed, we must know our future plans for serving the area involved. In other words, it is evident that a large amount of broad preliminary planning must be done before the detailed design of a telephone exchange plant can be undertaken.

It is the purpose of this paper to give a general idea of the methods now in use in this preliminary planning. The discussion will be confined to the exchange plant problem for the larger towns and will not go into the toll plant problem. To avoid confusion a "telephone exchange plant" will be defined as that plant serving a single community, for example, the "St. Louis exchange," or the "Kansas City exchange." An "operating center" will be defined as that part of the exchange plant housed in one building. There are thus several operating centers in a large exchange.

The first step in attacking the telephone planning problem for a city, is to make a determination as to about how much business will be cared for. This problem is attacked on very broad and thorough lines. An attempt is made to arrive at the estimated population of the city in question for some 18 or 20 years hence and also for intermediate periods of about 6 and 12 years. From these estimated future populations and other careful studies, which will be touched upon briefly later, an estimate is made as to the number of telephone stations and lines which will be in service 6, 12, and 20 years in the future. Moreover, this survey shows the location of these lines and stations.

It has been found that the various parts of a city have wide differences in market conditions or, in other words, the possibilities of selling telephone service. One of the first steps in making a survey is to divide the town up into so-called market areas or areas which display somewhat the same economic characteristics. These market areas are further broken down for convenience sake into what is known as "house-count sections."

The accompanying map (Fig. 1) indicates for an assumed case how a city is divided into market areas and house count sections for purposes of a survey. Market area "A," for example, would consist of the downtown business section which includes all the office buildings, department stores, hotels, and large retail firms together with some warehouses and manufacturing plants along the two railroad lines. Market area "H," for example, might be a residence area with the medium classes predominating, while market area "D" would consist of the highest type of residence district, including very little neighborhood business.

After the above divisions in the area of a city have been made, a card record is made of all the existing subscribers. These cards show the name, the telephone number, and the address of each subscriber. These data are then summarized on field survey sheets which are made up by blocks. The field men then

*Presented at the Regional Meeting of the A. I. E. E., St. Louis, Mo., March 7-9, 1928.*

take these sheets and go out into the field, visit the block covered by each sheet and for the business subscribers indicate the class of business, and for the residence subscribers the type of residence, and the estimated rental classification, that is, the estimated amount of rent that the subscriber is paying. The rental classification is merely a convenient means of arriving at some kind of an idea of the economic status of the family. It has been found that the market for telephone service is better among those subscribers who are better able to pay for this service and that there is rather a direct relation between the rental classification and the market for service in any one market area. This will be different for the various market areas, however. For example, a $40 rental in a market area inhabited by university people will represent a better market for telephone service than a $40 rental in an area inhabited by steel workers.

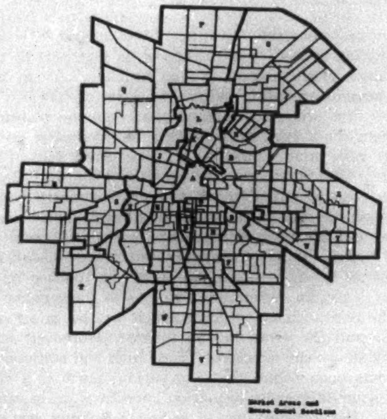

FIG. 1

These field sheets are later summarized so that we can tell about what percentage of the residence subscribers of the various classifications in the various market areas take telephone service and what class of service they take, that is, individual lines or party lines. These summaries also indicate the amount of neighborhood business and the amount of downtown business. The completion of the surveys then has given us very detailed information on the present market conditions for telephone service in the city in question.

In making an estimate for the future, the first and possibly one of the most difficult tasks is to arrive at an estimated population of the city for some 15 to 20 years hence. This problem is attacked on broad lines. Periodic estimates are made of the population of the United States, taking into account emigration, immigration, and the excess births over deaths. Similarly the estimated population of the United States is broken down by states and later distributed to the cities and other communities. This gives us the best possible estimate of the future population of the city in question. This estimate takes into account, not only local conditions, such as the trend of manufacturing, railroad facilities, etc., but also the national trend. These estimates of population are made in an impartial manner. Population estimates made by city boosters are inclined to be tinged with the hopes of the individual estimator, but every effort is taken to eliminate this factor from the estimates made for telephone purposes.

Data are at hand showing the average size of the families of the city in question and also the trend as to the increase or decrease in size of families. From the estimated future population, and estimated persons per family, the estimated number of families is obtained. Based upon the intimate knowledge of the city which was obtained in the survey, an estimate is made as to the number of families which will live in the various house-count sections in the city. Based upon the knowledge of the business in the town obtained from the survey and the relations which exist between business firms and residence population, an estimate of the future downtown and neighborhood business firms is obtained. From these residence and business data, an estimate of the future market for telephone service in the city is arrived at.

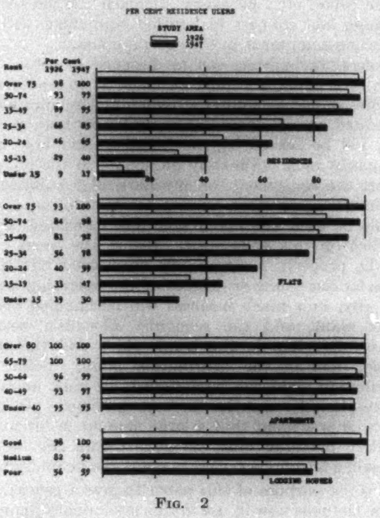

FIG. 2

It is thought that the accompanying Fig. 2 showing a typical per cent residence users will be interesting. It will be noted that the percentage of users in the various rental classifications is different for different kinds of dwellings, that is, residences, flats and apartments, and lodging houses.

A large map of the city is prepared and the estimated number of telephone lines for the future period is placed in each city block, which gives the best possible data for the planning of the telephone plant. The accompanying map (Fig. 3) is a spot map showing one spot for each ten telephone lines. The map has been prepared in spot map form since this will give a better idea of the telephone density than a map showing the number of lines in each block. The map showing numbers of lines is used in the actual calculations, of course, instead of the spot map.

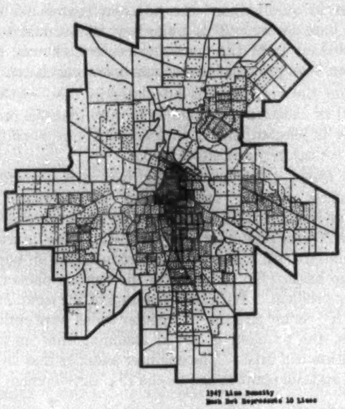

FIG. 3

The next problem is to determine the number of operating centers which will be required to serve the city and the best location for these operating centers. It would probably be physically possible to serve some of our larger cities from one operating center. This would involve an enormous equipment building at some central location and it would be necessary to provide cables connecting all the subscribers in the city to the one building. It is apparent that the average length of the subscribers' lines in this case would have to be very high. In order for the subscribers farthest from the operating center to be able to talk, it would be necessary to use wire of very large comparative diameters or take some other expensive means for eliminating undue transmission loss. In a city of perhaps 100,000 population, it might be necessary to consider seriously a single center plan, but it is obvious that in the case of the larger cities such an arrangement would be out of the question.

It would also be possible to go to the opposite extreme and place a little operating center in each block in the the city. In this case, the length of the subscribers' lines would be very short, being all less than one block long. All of these little centers, however, would have to be connected by trunks making a tremendously expensive trunk plant. Arrangements would have to be made to provide switching and transmission power at each one of these little centers and the cost of all of these little buildings would probably be much greater than the cost of fewer but larger buildings. This arrangement is obviously impossible from an economic standpoint and impracticable from a physical standpoint, and the correct answer is some place between the one center and many center plans.

The method followed in solving these problems, will be illustrated by assuming a sample problem and carrying through the line of reasoning. The sample problem is rather a simple problem for a small city, but exactly the same principles are involved as in the larger towns, such as St. Louis. This is the type of problem which is met today in most of our cities.

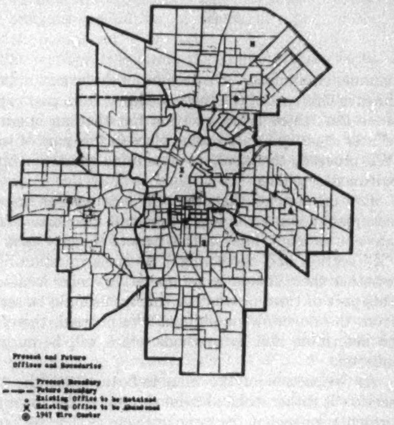

FIG. 4

The accompanying map (Fig. 4) indicates for our assumed problem the present centers, the present boundaries between the centers, and the future centers with the future boundaries which are determined by our studies.

Let us assume that the downtown "X" center has new dial type equipment housed in a new building. Very careful studies were made before this building was built, of course. A large investment is involved in this building and equipment which were designed so that they can be extended to last for many years. It is a safe assumption, therefore, that this building will be retained at its present location. Let us also assume that the "Y" operating center has just been built as a result of careful studies and is also designed to last for many years. On account of the large investment involved here, it is a safe assumption that this building will also be retained at its present location.

The "Z" building is several years old and houses manual equipment. On account of the large number of lines in this part of the town, we know from past experience that there is no question but that an operating center must be located some place in this part of town. We proceed, therefore, to determine what the future wire center will be.

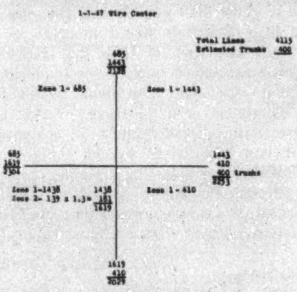

FIG. 5

Let us assume that the "M" center has manual equipment located in less permanent quarters. There are not so many lines in this part of the city as in the "Z" section and there might be some question as to whether there should be an operating center located in this part of town or whether this area should be served from the downtown building. We proceed, therefore, to determine this by methods which will be outlined later on.

An inspection of the map indicates that the "A" section is rather isolated from the rest of the town and presents somewhat the same problem as the "M" area, except that the "A" area is somewhat smaller and is now served from the downtown building. There is some question as to whether there should be a center in this part of town and we proceed with a solution of this problem together with a determination of the proper wire center.

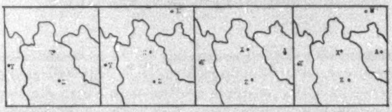
In the above paragraphs, the term "wire center" has been mentioned several times. A wire center may be defined as that location for an operating center at which the cost for subscribers' lines and trunks will be a minimum. The determination of a wire center is a cut-and try-problem which can be illustrated by the accompanying Fig. 5, illustrating the wire center for the "A" area.

From an inspection of the "A" area, a trial center is selected and axes are drawn on the map through this center following the direction of the principal streets. The lines in each quadrant are then equated in terms of the cost of the finest gage of conductor contemplated and summarized. The inter-office trunks are also included in this calculation. If it is found after these lines are counted that the sum of the equated lines in the various quadrants does not balance, a new center is tried to determine a better balance. When a balance is obtained, this point will be a wire center.

It is necessary to assume a boundary between the center in question and the adjacent centers for each trial wire center. This boundary is assumed to be equidistant from the operating centers, that is, each station is served from the nearest operating center.

After the wire center is calculated by these methods, practical checks are applied to be sure that the proper center is selected, taking into account local conditions as to topography and street layout.

In order to determine the best arrangement of operating centers, various trial arrangements are assumed, and certain costs involved in serving the city at the 20 year period (in this case 1947) in the future are calculated. All these costs are reduced to an annual charge basis. Fig. 6 indicates the various plans tried in our problem. With the exception of the locations of the "X" center and the "Y" center which were outlined above, the problem is solved assuming that an ideal condition will exist. The engineer assumes that he can build an ideal plant to handle the 1947 development and he has not taken into account any losses which might be occasioned due to the fact that the present plant would not fit in well with the ideal 1947 plant. The method of caring for the effect of the present plant will be outlined later on.



| PLAN I | PLAN II | PLAN III | PLAN IV |
|---|---|---|---|
| 3 Centers | 4 Centers | 4 Centers | 5 Centers |
| 7 Units | 7 Units | 7 Units | 7 Units |

FIG. 6—1947 COMPARISON

The above arrangements are compared as regards annual charges for each of the following items:

Subscribers' lines
Trunks
Central office equipment
Maintenance labor
Land

It is necessary that the trial arrangements of operating centers be chosen with great care, so that the comparison of the results of the various plans will give a direct comparison of the results of some possible program with some other possible program. In other words, each plan must differ from some other plan by one variable only.

By reference to Fig. 6, it will be found that plan No. 1 assumes an office at the present "X" location and at the present "Y" location. A center has also been assumed at the "Z" wire center which has been calculated as outlined above.

Plan No. 2 is exactly the same as plan No. 1 except that an "M" center has been added at the wire center of the "M" area. A comparison of plan No. 1 with plan No. 2 will therefore give a direct indication as to the economies of an "M" operating center.

Plan No. 3 is exactly the same as plan No. 1 except that a center has been added at the wire center of the "A" area. A comparison of plan No. 3 with plan No. 1 will, therefore, give a direct indication of the economies of having an operating center in the "A" area.

While plan No. 2 and plan No. 3 will give an indication as to the economies of an "M" or an "A" center, the downtown "X" center will be smaller, of course, if both the "M" and "A" centers are in existence than if only one of these centers were in existence. In order to check whether this would make any material difference in the economies of the arrangement of operating centers, a further plan No. 4 was prepared which assumes both an "M" and an "A" center.

Referring again to Fig. 6, it will be found that the first item of cost to be considered is that of subscribers lines or in other words, the cost of the conductors (including conduit) to connect the subscribers' telephone instruments with the operating center. The conductor requirements are determined for each plan, and suitable annual charges are applied. The annual cost of subscribers' lines is larger for any plan which has fewer centers since the only economy which can be obtained by opening an additional operating center, is a reduction in the cost of the subscribers' lines.

Whenever an additional center is added, it is necessary to connect this center by means of trunks to all the other centers in the city so that subscribers served from this new center can talk to any subscriber served by any other center. The trunk cost, therefore, will increase each time a center is added. An estimate is made of the flow of traffic between the various centers, from which estimate the number of trunks is derived. Knowing the grade trunk required to give proper transmission, the cost may be inferred.

Central office equipment is placed in the building at each operating center, of course, to furnish talking power to the subscribers and to furnish a means of switching connections between subscribers. The cost of the central office equipment increases somewhat when an additional center is added, due to the fact that it is necessary to provide a power plant and other common items of equipment for each building, and due to engineering and installation costs. In order to arrive at the equipment costs an estimate is made of the lines, terminals, originating calls, and calls trunked to and from other units of equipment, based on the estimated telephone development for the 20 year period. From these data, the requirements for various parts of the equipment are calculated and priced.

If a new operating center is opened, sufficient equipment would not be installed to last for the 20 year period covered in our growth estimates, of course, because the carrying charges on the idle equipment would be prohibitive. A considerably smaller amount of equipment would be installed, and additions would be made from time to time as required by the increasing number of subscribers.

An engineering and installation cost is involved each time an addition is made to this central office equipment. If more centers are added in a town, therefore, we will be adding equipment for growth to each of these centers, resulting in more but smaller additions. These engineering and installation costs do not decrease in proportion to the decrease in size of the addition; that is, these costs for a 2000 terminal addition will, in general, be more than one-half the cost for a 4000 terminal addition. Thus more centers will result in greater engineering and installation costs. These costs are capitalized, of course, as a part of the cost of the equipment.

In like manner, it is found that the operating costs, such as maintenance or other labor, and the costs of buildings and land are greater whenever an additional center is placed in a town. The maintenance labor is estimated by determining the number of men required and their salaries. Building costs are estimated by determining the required building volume.

Let us assume that the summation of the above annual charges for our problem indicates that Plan II and Plan III are each lower than Plan I (Fig. 6) and that Plan IV is also lower than either Plan II or Plan III. This indicates some economies for operating centers in the "M" and "A" areas as of 1947. As previously stated, the above calculations are based largely on being able to construct an ideal plant as of 1947 with no penalties due to the plant now in service. This is obviously an impossible condition and the above results, therefore, can be taken as only a broad general indication of the best method of serving the town. Obviously the above results give no indication as to when an operating center should be opened. It will be necessary to study each major move individually with the above results in mind.

Since there is already a center in the "M" area and the subscribers' cable is centered to this location, and since the indications are favorable to a center in this area for the 1947 period, there is little question but that the center should be continued. The present equipment is manual and the next big problem in this area will be to determine what to do when the manual unit is filled and cannot be extended without some major move.

In the "A" area (at present served from the downtown building), our assumption as to annual charges indicates that at some time it will probably be advisable to open an operating center. We have no indication, however, concerning at what time this center should be opened. We know from past experience that in general the best time to open a new center in an area is that time at which it would be necessary to make some major move if the center were not opened. For example, since the "A" area is fed from the downtown building, a time might arise when it would be necessary to make some major move downtown to handle the growth, such as a large building extension, with the possibility of postponing this move if a center were opened in the "A" area. On the other hand, the cable or conduit which feeds the "A" area might become filled so that a very large expenditure would be involved to reinforce these facilities if we continue to feed this area from the downtown building.

Let us assume that the latter condition exists in the "A" area. The feeder cables serving the section are located in conduit, the last duct of which will soon be used. It would be necessary to reinforce this conduit in the latter part of 1928 and place additional cable if the section were fed from the downtown building. This reinforcement will be expensive due to the fact that a portion of the reinforcement will involve rock digging. Knowing from the above studies that a center in the "A" section will probably be economical at some future time, the question immediately arises as to whether it would not be better to open this center in 1928 rather than to make the expensive conduit reinforcement and add more cable.

In order to solve this problem, reference is made to the estimated telephone development of the "A" area and the downtown area for the 20 year period and the intermediate periods, as developed from the commercial survey data. Based upon this estimated development, an estimate is made of all the building and equipment additions which would have to be made downtown between 1928 and 1947 both with and without an "A" center. An estimate is also made of the expenditures for conduit and cable which would be required, between 1928 and 1947, both with and without an "A" center. An estimate is made of the amount of equipment and the size of the building which it would be necessary to provide if the center were opened in 1928 and an estimate is also made of the additions which would have to be made to this building and equipment between 1928 and 1947. These various amounts of plant are priced and the annual charges are inferred. Since the investments and annual charges would vary between plans throughout the period between 1928 and 1946, the annual charges are placed on a present worth[2] basis. The following table indicates the results of this present worth study.

PRESENT WORTH 1929-1947

| | Plan I<br>Operate from "X" | Plan II<br>Open New Office |
|---|---|---|
| Aerial cable | $ 55,966 | $ 45,812 |
| Underground cable | 187,243 | 41,706 |
| Underground conduit | 59,868 | —— |
| Salvage on displaced plant | −26,559 | −42,521 |
| Building including house service | 28,922 | 108,678 |
| Land | —— | 4,306 |
| Central office equipment | 334,998 | 477,597 |
| Excess maintenance | —— | 69,883 |
| Number changes | 2,184 | 14,500 |
| Traffic saving | —— | −8,496 |
| Excess inter-office trunks | —— | 10,764 |
| Total | 642,622 | 722,229 |
| Excess | | 79,607 |

NOTE: The above does not indicate the total cost of serving the area, of course. The cost of much of the plant which will be required under either plan, has been omitted as being common to both plans.

This investigation, as summarized on the chart, tells us that, in so far as the various factors can be evaluated, the center should not be opened in 1928 but that the conduit should be reinforced and cable added instead. These data do not tell us when the center should be opened. It will be necessary to watch this situation in the future. and consider the problem again from time to time in much the same manner as above.

Since the data are available, the annual charges both with and without the "A" center are obtained for 1928 and for 1946. These annual charges are then plotted upon a graph as given in Fig. 7 and the annual charge points are connected by a straight line. It is appreciated, of course, that this annual charge will not be a straight line between 1928 and 1946 but will be irregular due to the periodical additions of plant and the straight line, therefore, is only a general indication. Our studies have told us, however, that if the "A" area grows as estimated, and if there are no unforeseen changes in the art, we will probably find it advisable to open an operating center in this area at some future date.

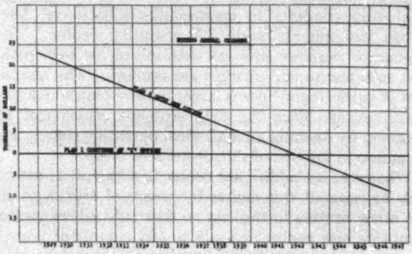


FIG. 7

The above discussion on the determination of the proper number of operating centers for a town and the determination of the wire centers for these operating

---

2. The present worth of a given sum of money due at the end of a given time is the sum that, put at compound interest for the given time, will amount to the given sum when due.

centers has indicated that the location for a telephone building is determined by the number and location of the subscribers to be served by that building. The number and location of the telephone subscribers is in turn the result of many factors, such as the topography of the town, real estate development, transportation, etc. It is apparent, therefore, that it will at times be necessary to build a telephone building in a residence area. When this is necessary, however, special care is taken to build a suitable and attractive building. The general architectural appearance is made to harmonize with the neighborhood. The set back in general use in the neighborhood is observed. Generous yards are provided, and these yards are made attractive by suitable treatment with shrubbery. In other words, every effort is made to make the building a welcome addition to the neighborhood.

The studies illustrated above have enabled us to reach the following conclusions:

1. The wire center in the "Z" area for the 1947 development is indicated by our calculations to be a considerable distance south of the present building. When it becomes necessary to erect a new building in this area, the trend of the future development, therefore, indicates that we should consider a location for the new building considerably south of the present building. The present building, of course, has been in service many years and was located as nearly as possible on the economical center for the development to be served by this building during its life. The new building, however, will serve a somewhat different area, and the trend of future development is towards the south.

2. We can conclude that there should be an operating center in the "M" area. The conditions in this case are somewhat similar to those in the "Z" area and will call for similar treatment in the light of conditions in the area.

3. We have determined that, from an economic standpoint, the conduit which feeds the "A" area should be reinforced in 1928 and additional cable placed between the area and the downtown building, thus deferring the opening of a new center in the "A" area for the time being.

4. We have obtained indications that it will probably be economical at some future date, to open an "A" center. It will be necessary to keep this in mind and make a further study of this question whenever it is necessary to make some major move which could be postponed if the center were opened.

Mention has been made above of the introduction of dial equipment in some of the offices. The question of when and how dial equipment should be introduced into an exchange is one which must be very carefully considered. As a general rule the most favorable time for the introduction of dial equipment is when it would be necessary to make some major move to care for the further growth in the area served by the operating center.

In developing the program to be followed in offices which are still on a manual basis consideration must, of course, be given when the necessity for a major move arises, to the question as to whether the use of this type of equipment should be extended for a further period or whether the dial type should be introduced.

It would, of course, be unwise from a physical and financial standpoint in one of the larger cities, St. Louis, for example, to undertake to change all of the manual equipment to dial equipment at one time. Since the manual equipment is entirely satisfacory for present conditions and much of it will be continued in service for some time it becomes necessary to devise interconnecting equipment whereby new operating centers as they are introduced may be of the dial type and be connected with and operated with the existing manual equipment. All of this has been satisfactorily accomplished and the costs of such equipment are reflected in the various cost studies.

There are two types of dial equipment, the so-called "panel" type equipment and the so-called "step-by-step" type equipment. Panel equipment has been designed primarily to meet the conditions in the larger exchanges, such as St. Louis, while step-by-step equipment is usually employed in the medium sized and smaller exchanges.

Referring to the above problem in the "M" and "Z" areas, careful studies made some time ago have indicated that the growth can be handled economically without any major moves by adding manual equipment. A major move will be required at "Z" when the manual unit is filled, when it will either be necessary to start a new manual unit or to start a new dial unit. Our studies outlined above indicate that if a new center is opened in the "Z" area, the building should be located about a mile south of the present building.

The problem in the "Z" area can be stated specifically as follows:

a. The "Z" area is served from one building which is considerably off the wire center for future development, for reasons previously outlined. The building houses one manual unit which will soon be filled, making it necessary to provide some major relief.

b. The preliminary indications are that the "Z" area should be served from one building in the vicinity of the wire center, overlooking for the moment the factors involved in making such a move.

Questions:

a. Should this new unit be located in an addition to the present building to conserve existing plant, or should a new building be erected nearer the wire center for the purpose of decreasing future investments in plant to care for future growth?

b. Should the new unit be of the manual or dial type?

c. In case the new unit is to be of the dial type, should enough equipment be installed for growth only, or should enough be installed to displace the manual unit?

In order to answer the above questions, it will be necessary to consider in detail each of several possible construction programs. Having determined the factors involved in the various possible programs, the engineer proceeds with the analysis of each of these programs. Possibly one or more programs can be eliminated due to practical considerations, and careful cost studies may eliminate other programs from an economic standpoint. In case cost studies are necessary, they will probably be of the present worth type, which was outlined above, for use in the question of opening a new center in the "A" area. In fact, this problem is somewhat similar to the problem outlined above for the "A" area, except that this problem is considerably more complicated, due to the presence of a building in the area. Taking all factors into account, one program is finally determined to be the most favorable to meet the needs of the particular situation.

Another type of problem has to do with the question of economic allocation of the transmission loss between the subscribers' plant and the trunk plant. This is determined by what are known as "loop and trunk studies." The data developed in connection with the commercial survey mentioned at the beginning of this paper together with comparable estimates of inter-office truck requirements, are largely used in the solution of this problem.

This problem is generally solved for an estimated development of a considerably less remote period than the 20 year figure used in some of our work. This is because the results of these studies are used for immediate engineering of extensions to the cable plant. The life of this plant in general is less than the life of central office buildings, and moreover it is relatively easy to make some adjustments in grade of conductors by making cable throws.

The estimated development indicates the numbers of lines which will be in service in each central office area at the future date selected and the lengths of these lines. Knowing the number of lines, the number and holding time of the calls flowing between offices are estimated and from this, the numbers of inter-office trunks on the various trunk routes are calculated.

In order that subscribers can talk satisfactorily in any exchange, the plant must be designed to conform with generally recognized transmission standards, these standards being set after individual consideration of all the factors peculiar to any one area. These standards represent a grade of transmission which experience has indicated will be thoroughly satisfactory to the subscriber and at the same time permit the development of an economical plant.

In a multi-center exchange area, the transmission loss is distributed principally between the subscribers' loops and the trunks, that of the station and central office equipment being relatively constant. In order to attain the desired standards, consideration must therefore be given to designs which will economically apportion the loss between the two classes of plant. It would be possible to provide the cheapest subscribers' plant available and make up the required transmission in an expensive trunking plant or vice versa. Obviously, either procedure would not permit of obtaining the desired transmission with an economically balanced plant.

Knowing the numbers and lengths of the lines and also the numbers and lengths of the various inter-office trunks required, as outlined above, the costs of the trunk and subscribers' plants are estimated on an annual charge basis for various distributions of the loss between the two types of plant. The transmission losses are then by successive trial distributed between the subscribers' loops and trunks and the total annual charges are estimated. These estimates will indicate which distribution involves the minimum total annual cost for both plants. This procedure is carried through for each central office in the exchange. The portion of the transmission loss (in T. U.) assigned to the subscribers' loops in each central office area is called the loop limit for that office.

This whole study is, of course, based on an ideal plant in the same manner as in the studies to determine the ultimate number and arrangement of offices in the exchange. Actually, the existing plant may differ materially. After the study is made, therefore, it is necessary to consider the plant actually in service and its effect upon the indications of the study before the limiting loops are finally decided upon.

The preliminary planning of telephone exchange plant has been discussed above largely from an economic standpoint and the discussion may have given the impression that the economics of the problem are given undue consideration. Such is not the case. It is obvious that any construction program must be considered from other angles as well as the economic angles. For example, if one program will result in better service to the public than another program, the program which would result in better service will receive instant and sympathetic consideration, even though this program might not be quite as attractive from an economic standpoint as some other program. Some programs require large amounts of capital, labor, and material, and it is obvious that such programs should be spread out to best advantage over a period of years.

Any program must be considered carefully to be sure that it is thoroughly practicable from a construction and operating standpoint. It is also desirable that all existing plant be used to best advantage, and when such plant is in good condition and would continue to give good service, it is generally desirable that such plant be retained until it has lived a normal life. To do otherwise would use up capital and result in rearrangements and changes which might not be desirable, even though such a course might show some small savings. In all of these considerations, of course, especially those involving rearrangements and changes, the factor of service to the public is given a very prominent place.

It is also important that the plans for the future extension of the plant be developed in a manner that will permit of a maximum of flexibility in caring for the future service requirements. Thus the characteristics of a plan must be such that suitable adjustments can be made economically in the event that the growth performance in the future varies materially from that upon which the plan was based. In other words, before commitments are made in line with any future plan, this plan is considered broadly from all angles and advantage taken of the knowledge and experience gained in the execution of similar plans.

It is hoped that the preceding outline of the broad general considerations of planning, together with the earlier outline of some of the economic features, will accomplish the purpose of this paper, which as previously stated is to give a general idea of the methods used in planning telephone exchange plants.

## Discussion

**E. N. Widen:** In discussing Mr. Stephenson's paper, I will confine myself to only one of the important questions upon which it touches, namely, the importance of population forecasting. People constitute the telephone market; therefore, forecasts of the future growth in the telephone market of a community must be based upon a consideration of the probable changes in the number and character of its inhabitants. In the telephone business, the importance of forecasting the future demand for service can hardly be overemphasized for two reasons: first, an obligation rests upon a telephone company to deliver service when and where it is needed; second, sound population forecasts are essential if the losses incident to over-built or under-built exchanges are to be avoided.

The telephone plant, especially in large communities, is each year becoming less susceptible as a whole to radical changes in basic plans, a fact which further emphasizes the importance of appraising the future market carefully. Other utilities, including electric light and power companies, gas companies, and street railways, are faced with practically the same problem in estimating their future market. Incidentally, the need for population forecasting in city planning might be mentioned, a fact emphasized by the necessity now existing in many of our large cities for costly street-widening projects and the provision of plazas and parks in sections already built.

Business generally, I believe, has become more forward-looking. Manufacturing programs, sales plans, and financing arrangements of large concerns all are based more or less upon forecasts of the volume of business done. However, the importance of forecasting the future volume of business varies widely in different types of industries. A shoe manufacturer, for example, may be utterly mistaken in his ideas of the volume of business to be secured in certain communities; perhaps his expectations are much too high in some instances and much too low in others. Yet, because the manufacturer has no fixed capital investment in the particular communities, such errors in judgment may be of no serious consequences whatever.

Again, if a large distributor finds business below expectations in some of his markets and above expectations in others, he can, with no great inconvenience, concentrate his efforts on the better markets. But the problem is a different one for the telephone company and other utilities. If a city grows far more rapidly than was anticipated, or if its growth comes in unexpected sections, the utilities serving it naturally require a period for planning and installing the facilities necessary to meet the unexpected conditions. In other words, the utilities, with their heavy fixed capital investments, have less flexibility than do most other kinds of industries.

Population forecasting is not a simple undertaking. On the contrary, it requires the most searching analysis of economic resources and economic trends. What most probably will occur to influence population changes is always the first consideration in forecasting the population of a community; sound forecasts cannot be based upon what could or should be done. Moreover, such forecasts cannot be made to rest upon a local point of view. The principal population-supporting activities of a community must be considered from a national and even an international point of view; such procedure ordinarily leads to less optimistic conclusions than those reached by mere local judgment, but they are more likely to be realized.

It must be recognized that cities and regions are in direct competition with each other for shares of the total growth of the country, and that comparative, not absolute advantages are the determining factors. Incidentally, I might mention that the Bell System, in order to improve its population-forecasting work, has undertaken systematic and comprehensive studies of economic changes affecting the number and distribution of the nation's population. As a phase of this work, in the Southwestern Bell Telephone Company, we are making economic surveys of each of the five states in which we operate.

In addition to forecasting the population of a community as a whole, the telephone company has the problem of forecasting the distribution of population within a city. For this purpose it is necessary to consider such questions as transit conditions, probabilities of transit improvements, the availability and desirability of vacant land, and the probable reconstruction and crowding, or perhaps thinning out of population in the older sections. Any forecast of future demand for service requires an appraisal or gradation of the market, with the present and future character of the population assigned to each small area of the city. All this is, of course, essential to the proper layout of the telephone plant. The analysis of the present and future market is likewise fundamental to the proper planning of a sales program.

Everyone recognizes that many uncertainties attend the making of population forecasts. We cannot estimate for accidents nor in long-range forecasting can we estimate for accelerations and delays due to temporary business conditions. Meticulous precision is impossible, but we believe that a working knowledge of conditions in the future is not only a possible and practical thing, but something essential to the intelligent conduct of the telephone business.

**G. J. Vande Steeg:** Mr. Stephenson has stated that it would be unwise from a physical and financial standpoint to undertake a complete conversion in our larger cities from manual to dial-type equipment at one time. Several elements, of course, contribute toward making such a course unwise. One of these is the manufacturing situation and it may be well to discuss briefly some of its aspects.

For the purpose of discussion, we will include, under manufacture, all of the activities in connection with the provision of materials or apparatus, until these are made available to a telephone user. We start, then, with the purchase and assembly of raw materials. This is an extremely important item as the Bell System factories annually require vast quantities of almost all kinds of materials. The yearly requirements for some of the more common and familiar items will indicate the magnitude of this phase of the manufacturer's problem. Among the leading items are steel, 22,000,000 lb.; antimony, 2,000,000 lb.; silk and cotton yarns, 4,000,000 lb.; lumber products, 24,000,000 board ft. The manufacturer of lead-covered cable each year requires 170,000,000 lb. of paper, lead, and copper. Should a complete conversion to dial equipment at one time be found desirable in our larger cities, simultaneous conversions in other large cities in the country might be reasonably expected, resulting in abnormal demands for raw materials with the usual reactions on prices.

The processes of converting raw materials into items useful in the telephone plant are varied and in some cases extremely complex, requiring the services of a personnel ranging from unskilled labor to highly specialized and trained technicians. In the case of dial central-office equipment, the manufacturer installs the equipment. This work requires a force of trained experts and special testing apparatus, to insure satisfactory operation of the equipment when it is turned over to the telephone company.

These points are brought out to indicate the manufacturers' connection with conversion projects so that the desirability of scheduling these projects to insure as nearly as possible a uniform factory load may be apparent. In order to permit the manufacturers to procure raw materials advantageously and to lay out a uniform program of manufacture and training of factory and installation personnel, it is essential that the major conversion projects be scheduled far enough in advance and the program planned to avoid as far as possible excessive peaks in factory loads. Such a program benefits the purchaser in that a better product can be obtained at a lower cost.

It is apparent, I believe, that the manufacturing problems should be given weight in laying out a conversion program. The difficulties and penalties are, however, not controlling and should the desirability of a complete conversion be indicated by thorough consideration of all the factors, the manufacturing difficulties can be overcome.

**H. R. Fritz:** Mr Stephenson, in his paper, referred to loop and trunk studies which are made to determine the economical distribution of the exchange plant between trunks and subscribers' loops in multi-office areas. Such studies assume the use of the most efficient type of subscribers' instruments available at the time. Such an assumption is necessary in order that the most economical use may be made of the cheaper small gage cable.

Continuous improvement has been made in the efficiency of transmitters, receivers, and in the coordinated design of subsets. From time to time, there are made available instruments of such improved efficiency, which are introduced into the plant. The result is that there are now in use several instrument combinations which differ considerably in transmission efficiency. As the limiting loops are established on the basis of using the most efficient type of apparatus, it is obvious that these several types of instruments cannot be used in an indiscriminate manner. To do so and still maintain the necessary transmission standard would mean that the cable plant would have to be designed for the least efficient of the sets.

To avoid this uneconomical procedure and still permit the efficient use of available types of instruments, it is the practise to establish definite zones in each exchange area for the several instrument combinations. Basing these zones on the use of 24-gage cable, the least efficient subsets are restricted to the zone nearest the central office.

The limit of this inner zone is determined by the length of 25-gage cable, which can be used without exceeding the limiting transmission for any particular office. Beyond this limit, a second zone is established, in which subsets of the next higher grade are used. Finally, a third or outer zone requires the use of the most efficient types of instruments. When the limiting loop has been reached with 24-gage in this zone, use is made of combinations of 24- and 22-gage, all 22-gage, combinations of 22 and 19-gage, and finally all 19-gage cable. Loops of such length that the desired transmission cannot be given with 19-gage conductors and the most efficient type of instruments, are given special consideration and the most suitable means for treating them are applied.

This method of zoning instruments permits the maximum and most economical use of the several gages of exchange cable without having to abandon the use of the less efficient subsets. As future improvements in the efficiency of subsets become available, it will be possible to extend the use of small-gage cables, resulting in further economies in the cost of exchange plant.

As mentioned in Mr. Stephenson's paper, the loop and trunk study envisages an ideal plant. The same is true of the instrument zones. Actually, of course, the existing cable plant is not distributed in the manner assumed in establishing limiting loops and laying out the zones. As a rule, there is in the plant a considerably larger amount of 22- and 19-gage cable than required in the ideal plant. This may lead to the temporary establishment of limiting loops and instrument zones different from the ideal. Also, ringing and common battery supervision requirements may modify the use of an ideal cable plant based only on transmission. However, all new plants and additions to existing plants are engineered to conform with the ideal arrangement. Instruments are zoned in the same manner, either on a routine basis or by wholesale changes, depending on circumstances.

# A Thermal Method of Standardizing
## Dielectric Power Loss Measuring Equipment

BY J. A. SCOTT[1], H. W. BOUSMAN[1], and R. R. BENEDICT[2]
Associate, A. I. E. E. Associate, A. I. E. E. Associate, A. I. E. E.

***Synopsis.**—After a brief review of the need for reference standards in dielectric power-loss measurements at high voltage and commercial power frequencies, this paper describes a thermal method for measuring dielectric power loss in cable, utilizing the sheath temperature rise associated with the flow of heat due to the power loss within the sheath. Sources of error are discussed briefly, and results are given in comparison with measurements of dielectric power loss by the reflecting astatic electrodynamometer wattmeter using an air capacitor for phase-angle compensation.*

*In connection with the investigation, certain possible errors in dynamometer measurements are noted, particularly the effect of humidity on power loss in the air capacitor.*

### GENERAL

FOR some years, engineers interested in the measurement of dielectric power loss at high voltage and commercial power frequencies, such as in paper-insulated cable, have felt the need for suitable means by which such measurements could be standardized. Until stable standard loads as described by Mr. F. M. Farmer at the Madison Regional Meeting of the Institute in 1926[3] were prepared and circulated among the various laboratories and factories interested, no such reference standards were available. These loads are sufficiently permanent to promise substantial agreement up to 20 kv. among those making dielectric power-loss measurements, which was not the case when cable samples were exchanged for this purpose. It is hoped that similar standard loads will be developed for higher voltages. These, however, are reference standards only. Dielectric power-loss measurements should be standardized in terms of well established units if possible.

It is considered that a check on dielectric power loss may be made with considerable accuracy by examining the heat appearing in the dielectric under consideration. The methods that occur to one as promising are either (1) a flow calorimeter or (2) the comparison of surface temperature rise of two samples under similar conditions,—one having dielectric power loss; the other, a source of heat easily measured with the desired accuracy, such as d-c. ohmic power loss in the conductor. When the temperature rises are equal, the dielectric power loss in the former is taken equal to the ohmic power loss in the latter. The symmetrical geometry of lead sheathed cable and the ease of making measurements on a short section of a long cable (thus avoiding end effects), led to the adoption of the latter method which will be known in this paper as "comparison of heating." Results of preliminary measurements by comparison of heating at about 35 kv. three-phase were presented by Mr. E. S. Lee in the discussion of the Symposium on Dielectrics and Power Factor Measurements held at the Niagara Falls Regional Meeting of the Institute in 1926.[4] The present investigation extends this method to single-phase measurements at 90 kv., and introduces refinements in the apparatus and method.

It should be noted that our immediate interest in this work was the detection of any constant error in the dynamometer wattmeter equipment as used for the measurement of dielectric power loss in high-voltage cable.[5] Due to this interest, several other phenomena not closely connected with the thermal measurement of dielectric power loss, especially the fairly definite loss in the air capacitor at high relative humidity, were examined and are reported here.

This paper is presented that others interested in dielectric power-loss measurements at high-voltage and commercial power frequencies may avail themselves of our experiences with this method as a means of checking dielectric power-loss measuring equipment.

### DESCRIPTION OF APPARATUS

Comparison of heating requires the measurement of the ohmic power loss in the conductor of one cable which produces nearly the same sheath temperature rise as that of a similar cable to which alternating voltage is applied across the insulation, the cables being under like conditions for heat flow to the surrounding medium; that is, two like cable samples with suitable terminals are required, mounted in some medium that provides approximately constant ambient temperature and like conditions for heat flow from the two cables. Means must be provided for the measurement with necessary accuracy of the small temperature difference between the two sheaths. Actual temperature rises are not needed if the condition of constant equal ambient temperature and thermal emissivities constant in time can be maintained. Air is not necessarily the best medium of those suggested to meet these conditions, but it was found quite satisfactory in the apparatus described below.

A room with thermostatically-controlled heaters was available for the test. With the thermostat set for 33 deg. cent., and the air in the laboratory at about 27 deg. cent., (normal summer condition), the air in the lower part of the room went through cycles of about 20-min. duration with a maximum temperature difference of 0.6 deg. cent. The average temperature of the various cycles varied through a range not exceeding 0.1 deg. cent. with the latter part of the day usually a few hundredths of a degree hotter. In this room were placed two 30-ft. (9.2-m.) lengths of 750,000-cir. mil (380 sq. mm.) stranded-conductor lead-sheathed cable, insulated with 0.750-in. (19 mm.) oil treated paper; 10-ft. (3.05 m.) measuring sections at the middle of each length were insulated by cutting out about ⅜ in. (0.9 cm.) of lead and filling the space with gum rubber. These measuring sections were supported near the floor (Fig. 1) and enclosed in a tight paper box. This paper box (shown with the top rolled back in the figure) served to reduce the cyclic variation of ambient temperature from 0.6 deg. cent. to less than 0.2 deg. cent. The cable ends were carried up to suitable terminals on the roof and the sheaths beyond the measuring section, together with a network of piping and low-voltage wiring conduit on the ceiling, carefully grounded, thus providing electrostatic shielding of the measuring section.

Fig. 1—Cable Samples Arranged for Dielectric Power Loss Measurement by Comparison of Heating

Two schemes of temperature measurements were used. Four sets of thermopiles, each consisting of 20 copper ideal junctions in series, 10 "hot" junctions embedded in the sheath of one cable and 10 "cold" junctions in the other, were distributed along the measuring sections of the cables to permit reading temperature differences. The second scheme consisted of five resistance temperature detectors made of 10-mil (0.065 sq. mm.) enameled copper wire wound in contact with the sheath of each cable and covered with a strip of 0.010-in. (0.25 mm.) horn fiber. The thermopile e. m. fs. were obtained from observation of the deflection of a galvanometer of suitable sensitivity in series, taking deflection in both directions.

A potentiometer was used to measure resistance temperature detector resistances. It appeared to have some advantage over a bridge for the low-resistance (10 ohms) detector used.

Direct current was circulated through the conductor of one cable from a motor-generator run from a "constant voltage" supply, with manual control to supplement the voltage regulator. The power dissipated in the cable conductor was measured with portable ammeter and millivoltmeter carefully calibrated. Alternating high voltage of 60-cycle frequency was impressed on the other cable from a 70-kv-a. testing transformer supplied from a generator of good wave form. Voltage measurement was by means of a portable dynamometer type voltmeter connected to the voltmeter coil of the testing transformer and checked against the potential transformer and voltmeter of the dielectric power loss dynamometer wattmeter equipment.

## HEAT FLOW

Two questions may well arise here concerning the necessity for approximately constant ambient temperature and the possibility of error due to axial flow of heat along the conductor. Constant ambient temperature is necessary because the dielectric power loss in paper-insulated cables at a given voltage changes with temperature and because, of the two cables, the one heated by dielectric power loss will respond more rapidly to changes in ambient temperature than the one heated by copper loss. Fig. 2, showing temperature difference as a function of time between two cables having dielectric power loss in one very slightly less than the ohmic power loss in the conductor of the other, illustrates this.

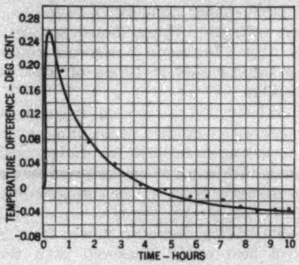

Fig. 2—Temperature Difference between Cable Sheaths as a Function of Time

Ordinate is temperature of cable sheath *A* minus temperature of cable sheath *B*, with dielectric power loss in cable *A* nearly equal to ohmic loss in conductor of cable *B*

The possibility of error due to axial flow of heat along the conductor may be considered from the standpoint of the following approximate analysis of steady state conditions:

Refer to Fig. 3, which shows a length, $2L$, of single-conductor cable whose axis lies along the x-axis and whose center is at the origin.

$a$ = radius of conductor. (cm.)
$b$ = outer radius of insulation. (cm.)
$\alpha$ = thermal conductivity of conductor (calories per second through a cm. cube per deg. cent. between faces)
$\beta$ = thermal conductivity of insulation. (calories per second through a cm. cube per deg. cent. between faces)
$\theta_1$ = temperature of a point on surface of conductor. (deg. cent.)
$\theta$ = temperature at a point in insulation, coordinates $x, r$. (deg. cent.)
$\rho$ = source of heat, calories per cu. cm. per sec. in conductor.

Neglect radial temperature drop in conductor.

Neglect axial temperature drop in insulation.

Boundary conditions. $\theta = 0$ at $r = b$

$$\theta = \theta_1 = 0 \text{ at } x = L$$

$$\frac{d\ \theta_1}{dx} = 0 \text{ at } x = 0$$

Take a disk element of small thickness $\Delta x$; the flux of heat in the radial direction out of the element[6] equals $\Delta H_r$

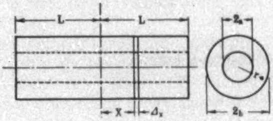

FIG. 3—DIAGRAM FOR AXIAL HEAT FLOW CALCULATIONS

$$\Delta H_r = \frac{2\,\pi\,\beta\,\theta_1}{\log\dfrac{b}{a}}\,\Delta x \qquad \text{(calories per sec.)}$$

The flux of heat in the axial direction out of the element equals $\Delta H_x$.

$$\Delta H_x = -\,\pi\,a^2\,\alpha\,\frac{d^2\,\theta_1}{dx^2}\,\Delta x \qquad \text{(calories per sec.)}$$

Heat appearing in element $= \pi\,a^2\,\rho\,\Delta x$ (calories per sec.)

Then, since the heat leaving the element equals the heat appearing in the element,

$$-\frac{d^2\,\theta_1}{dx^2} + \frac{2}{a^2\left(\log\dfrac{b}{a}\right)}\,\frac{\beta}{\alpha}\,\theta_1 = -\frac{\rho}{\alpha}$$

Solving and substituting boundary conditions

$$\theta_1 = \theta_m\left(1 - \frac{\cosh w\,x}{\cosh w\,L}\right)$$

where $$w = \left(\frac{2}{a^2\left(\log\dfrac{b}{a}\right)}\,\frac{\beta}{\alpha}\right)^{1/2}$$

and $\theta_m$ = temperature of conductor in an infinitely long cable with the same $\rho$ in its conductor; *i. e.*,

$$\theta_m = \frac{\rho\,a^2\log\dfrac{b}{a}}{2\,\beta}$$

In this cable, $w$ = approx. 0.028
$\alpha$ = approx. 1.0 $\quad L = 460$ cm.
$\beta$ = approx. $500 \times 10^{-6}$ $\quad w\,L = 13$

At the end of the measuring section, $x = 152$ cm., and $w\,x = 4.3$

$$\theta_1 = \theta_m\left(1 - \frac{\cosh 4.3}{\cosh 13}\right) = 0.9993\ \theta_m$$

That is, the conductor temperature at the ends of the measuring sections of these cable samples is 0.999 times the temperature that would be reached if there were no axial flow of heat. Thus, for our purpose, flow of heat may be regarded as radial.

### PRECISION OF MEASUREMENT

D-c. power input measurements, as such, call for no further comment. They are of the precision usually obtained with portable instruments and ordinary care. It is necessary to note, however, that, with our equipment, this power input could not be held constant during a heat run as closely as it could be read on the instruments. Momentary departures from the desired value of power input were as great as one and one-half per cent. The same figure holds for departure from the desired value of voltage squared on the cable having dielectric loss. It is believed that over a short period, the mean power was held to within one part in two hundred, though one per cent is reported here as a conservative value for probable error in holding constant power on each cable separately.

Cable charging current, although not entering into the determination of dielectric power loss, was measured, using an electro-dynamometer ammeter with an accuracy of one per cent. The same value of current at a given voltage, obtained from a series of determinations, was used in calculating all power factors at that voltage.

Temperature differences by thermopile were read by a galvanometer. The over-all sensitivity was 0.0015 deg. cent. per mm. deflection. Errors due to thermal e. m. fs. in the galvanometer and series resistance, (used to secure proper damping), were eliminated by reversed readings. Connection to the thermopiles was made by means of copper braid clipped directly to the copper wire leads from the thermopiles. There is here a source of possible thermal e. m. fs. not eliminated by reversed readings. This source of error was investigated and found small as compared with one mm. deflection.

In view of the fact that the resistance temperature detectors were read one at a time, it was necessary to follow a scheme of checking back, reading first a detector on cable $A$, then one on cable $B$, then back again to $A$, in order to avoid errors due to the small cyclic variations in ambient temperature previously mentioned. This variation amounted to about 0.03 deg. cent. at the detectors (0.2 deg. cent. in the air). The sensitivity was about the same as for thermopiles, *i. e.*, readings could be taken quite rapidly to 0.002 deg. cent. Incidentally, the labor of computation is considerably greater with resistance temperature detectors.

Sensitivity of this order, since it was easily obtained, was considered desirable even though it was a little better than the accuracy with which temperature rises could be held; this is, 0.002 deg. cent. represented about 0.001 watt per ft. length of cable, or not over one-fourth of one per cent of the loss in the cable. Control of loss was not quite so close; say, less than one per cent. It is believed that the cyclic variation of ambient temperature led to no constant errors, though it undoubtedly increased the deviation of individual readings from the mean.

Measurements of dielectric power loss on this cable were made with the dynamometer wattmeter measuring equipment under temperature conditions as nearly like those obtaining on comparison of heating as possible. This, together with the close agreement between various dynamometer wattmeter measurements made over a period of five weeks, is believed to eliminate the possibility of serious error due to change in dielectric power loss in the samples. These measurements are recorded in Table I.

TABLE I

DYNAMOMETER WATTMETER MEASUREMENTS OF POWER FACTOR OF CABLES ARRANGED FOR COMPARISON OF HEATING:

Power factor. Cable *A*

| Date | 45 kv. | 60 kv. | 75 kv. | 82.5 kv. | 90 kv. | 100 kv. |
|---|---|---|---|---|---|---|
| 8-2 | $0.0034_0$ | $0.0034_5$ | $0.0035_3$ | .. | .. | .. |
| 8-24 | $0.0032_8$ | $0.0034_0$ | $0.0033_6$ | $0.0033_6$ | $0.0033_6$ | .. |
| 8-25 | $0.0033_6$ | $0.0032_3$ | $0.0033_9$ | $0.0030_8$ | $0.0032_4$ | $0.0034_6$ |
| 9-30 | .. | .. | $0.0032_6$ | $0.0032_5$ | $0.0032_5$ | .. |
| 10-1 | .. | .. | $0.0032_8$ | $0.0032_0$ | $0.0031_8$ | .. |
| | Average | | $0.0033_5$ | $0.0032_2$ | $0.0032_5$ | |

Power factor. Cable *B*

| Date | 45 kv. | 60 kv. | 75 kv. | 82.5 kv. | 90 kv. | 100 kv. |
|---|---|---|---|---|---|---|
| 8-2 | $0.0034_2$ | $0.0031_1$ | $0.0034_2$ | .. | .. | .. |
| 8-24 | $0.0033_4$ | $0.0033_6$ | $0.0034_7$ | $0.0035_2$ | $0.0035_6$ | .. |
| 8-25 | $0.0034_0$ | $0.0033_0$ | $0.0035_8$ | $0.0034_9$ | $0.0035_9$ | $0.0037_6$ |
| 9-30 | .. | .. | $0.0033_2$ | $0.0033_5$ | $0.0033_6$ | .. |
| 10-1 | .. | .. | $0.0032_8$ | $0.0032_8$ | $0.0032_8$ | .. |
| | Average | | $0.0034_1$ | $0.0033_9$ | $0.0034_2$ | |

As a numerical value for error in any one measurement of dielectric power loss by comparison of heating, assume equal weights for one per cent error in holding d-c. power input constant, one per cent error in holding square of impressed voltage constant, and one and one-half per cent error in power corresponding to one-half the cyclic variation of sheath temperature (0.03 deg. cent.)

$$((0.01)^2 + (0.01)^2 + (0.015)^2)^{1/2} = 0.0206$$

or two per cent expected error in final dielectric power-loss measurement. In this cable sample, this is about two-thirds of 0.0001 power factor.

The error in a dynamometer wattmeter measurement, assuming correct phase-angle error compensation, is taken equal to 0.0002 power factor for samples of this size with the dynamometer wattmeter equipment used in this investigation. Thus, a difference between power factor calculated from dielectric power loss by comparison of heating and power factor from dynamometer wattmeter power measurement, greater than 0.0003 power factor, would call for explanation.

## THEORY CONCERNING HEAT EMISSION

Consider two cables, *A* and *B*, set up as described and in thermal equilibrium.

$P$ = loss, watts per cm. length in *A*

$Q$ = loss, watts per cm. length in *B*

$a$ = "thermal emissivity" of *A*, watts per cm. length per deg. cent.

$b$ = "thermal emissivity" of *B*, watts per cm. length per deg. cent.

$\alpha$ = temperature rise *A*, deg. cent.

$\beta$ = temperature rise *B*, deg. cent.

$$\theta = \alpha - \beta$$

$$P = a\,\alpha$$

$$Q = b\,\beta = b\,\alpha - b\,\theta$$

$$Q = P\frac{b}{a} - b\,\theta \qquad (1)$$

or, if $P$ is unknown, $Q$ known,

$$P = Q\,\frac{a}{b} + a\,\theta \qquad (2)$$

$a$ and $b$ may be thought of as somewhat fictitious emissivities invented as a tool for handling quantitatively the consistent small differences in temperature rise that appear when two pieces of cables from the same reel are laid side by side and dissipate equal amounts of power.

These differences would not be expected to be the same for any two sets of temperature detectors applied to the lead sheath but they are considered constant in time if the apparatus is not handled or moved; that is, values of $a$, $b$, and $\theta$ (Equations (1) and (2)) obtained with one set of temperature detectors differ from values obtained with another set of temperature detectors, yet resulting values of $P$ or $Q$ might be approximately the same.

## EXPERIMENTAL RESULTS

Five runs with direct current in each cable were made to provide data for the determination of $a$, $b$, and $\frac{a}{b}$ although only two were necessary to solve for these constants from equations (**1**) or (**2**). The additional runs were made to verify their constancy in time. Results are shown in Table II.

These were followed by six runs, (a "run" referring to the maintenance of a definite current in one cable and voltage on the other cable for the time, about 10 hours, required to reach approximate thermal equilibrium), the results of which are tabulated in Table III.

In this table "th" refers to thermopile determinations. "R. T. D." to resistance temperature detector determination, and "Dyn." to measurement of dielectric power loss by dynamometer wattmeter with air capacitor for compensation. $\theta$ refers to equations (**1**) and (**2**). Note that one run was made on each cable at each voltage as a further precaution against error or change in $a$ and $b$, the thermal emissivities. To aid rapid analysis, power factor results from this table are plotted in Fig. 4.

The two methods agree within nine per cent in any case, or within six per cent for average of all cases. This agreement is at about 0.003 power factor and represents a difference of 0.0002 power factor.

° Cable $B$

Solid line (————) represents power factor determined from dielectric power loss measurement by comparison of heating.

Broken line (- - - - - - -) represents power factor from dynamometer wattmeter measurement of dielectric power loss

### Application of Results

The comparison of heating measurements were made primarily as a precise check on the dynamometer wattmeter equipment for dielectric power-loss measurement. To make the fullest possible use of this check and to avoid the necessity for frequent repetition of comparison of heating measurements it became desirable that certain possible sources of error in the use of the air capacitor for phase-angle compensation of the dynamometer wattmeter be examined critically and the error reduced to a negligible amount. This work is discussed under two headings: (1) The effect of phase displacement between capacitor charging current and current through the dynamometer wattmeter current coils is under "Review of Compensated Dynamometer Wattmeter Measurement of Dielectric Power Loss," and (2) the fairly definite power loss in the air capacitor at high relative humidity is under "Effect of Humidity on an Air Capacitor."

### Review of Compensated Dynamometer Wattmeter Measurement of Dielectric Power Loss

A brief review of the compensated dynamometer wattmeter method of measurement of dielectric power loss will be of assistance in an examination of the errors which may arise, particularly those associated with high humidity. Fig. 5 shows the connection diagram of the capacitor and measuring circuit described heretofore.[5,7] The guard rings $G$ completely screen the low-voltage plates $B$ from all electric fields other than that from the high-voltage plate $A$. Theoretically $G$ should be at the same potential as $B$. Practically, grounding $G$ introduces no error that can be read, as shown here. If the DPDT switch indicated on the diagram is thrown to position $M$, capacitor charging current less that part of it shunted through the capacitance and leakage resistance (see Fig. 6), from low-voltage plate to ground flows through the current coils of dynamometer $D$. Then $Z_p$ may be adjusted in phase angle for zero deflection of the dynamometer, indicating a 90-deg. phase angle between dynamometer potential coil current and dynamometer current coil current. This will also indicate a 90-deg. phase angle between dynamometer potential coil current and the charging current of a pure capacitance if the air capacitor $A$-$B$ has negligible loss, the capacitance $B$-$G$ from low-voltage plates to guard ring is negligibly small and the leakage resistance $R$ from low-voltage plates to guard ring is sufficiently high. If $R$ is large compared to the impedance of the dynamometer wattmeter current coils, $R_c + X_c$, the phase difference between currents $I_1$, and $I_c$, Fig. 6, may be regarded as $X_c/R$.

The minimum value found by measurement for $R$ is 50 megohms. This observed value occurred at 70 per cent relative humidity and 26.5 deg. cent. The dynamometer wattmeter current coil reactance, $X_c$, is 93.5 ohms at 60 cycles.

$$\text{Phase difference} = \frac{X_c}{R} = \frac{93.5}{50 \times 10^6} = 0.000002.$$

Making the usual assumption concerning very small angles that the angle, its sine, and its tangent, are all equal, this is a power factor error of 0.000002, which is clearly negligible as compared with 0.0002 power factor measurable with the dynamometer wattmeter equipment.

The capacitance $B$-$G$ from low-voltage plate to guard ring, including leads, is approximately 1300 $\mu\mu$f. or 2-megohms reactance at 60 cycles. Dynamometer wattmeter current coil resistance, $R_c$, is 162 ohms. The phase difference between currents $I$ and $I_1$ is then approximately

$$\frac{162}{2\times 10^6} = 0.00008$$

This is a power-factor error of less than 0.0001, which is nearly significant but not large enough to read on the dynamometer wattmeter. Note that a similar phase displacement in the same direction occurs when the cable sample is connected to the dynamometer wattmeter. With ordinary guard ring construction, the capacitance from sheath to ground is usually smaller than that from low plate to ground of the air capacitor; thus, it tends to reduce the total error. Special tests must be watched carefully to see that this capacitance does not exceed reasonable values, say twice that from low plate to ground of the air capacitor.

## Effect of Humidity on an Air Capacitor

Observation of the performance of several high-voltage air capacitors used for dielectric power-loss measurement shows occasional conflicting results on damp summer days. These cases of suspected error, although infrequent, make all dielectric power-loss measurements in terms of an air capacitor subject to doubt until the conditions associated with them can be stated. An examination of the technical literature fails to show that such doubtful readings have been ascribed to actual power loss in very humid air, but in each such case, humidity probably varied to a greater extent than did other conditions. Hence, it seemed well to investigate the effect of humidity on an air capacitor used for phase-angle compensation of the dynamometer wattmeter for dielectric power-loss measurement.

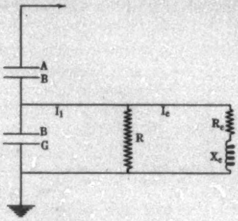

Fig. 6—Equivalent Circuit, Air Capacitor, and Instrument

While the comparison of heating measurements were under way, such an air capacitor, as described in detail elsewhere, was enclosed in a tight box equipped with means for controlling and measuring humidity. Humidity was increased by slowly introducing water vapor into a circulating air stream within the box or decreased by exposing calcium chloride in the box. Measurement was by wet and dry bulb thermometer in the air stream. In each case, time was allowed for the humidity of the air between the capacitor plates to assume a steady-state value.

The capacitor was used at various relative humidities and temperatures to compensate the dynamometer wattmeter for measurement of the apparent dielectric power loss and power factor of the cables previously standardized by comparison of heating. The power factor of either of these cables as measured repeatedly by dynamometer wattmeter with the air in the capaci-

tor dry was assumed constant. (See Table III and Fig. 4). The difference between the assumed constant power factor and that measured when a given humidity and temperature existed in the air between the capacitor plates was taken as the "power factor" of the air capacitor at that humidity and temperature, indicating an actual power loss between the plates of the capacitor. Results of such measurements are shown plotted on Figs. 7 and 8. Considering the nature of the measurements involved, it is felt that these results are sufficiently consistent to warrant the conclusion that the capacitor is practically without loss below 50 per cent relative humidity, and shows a very marked power loss above 50 per cent relative humidity, larger at greater humidities.

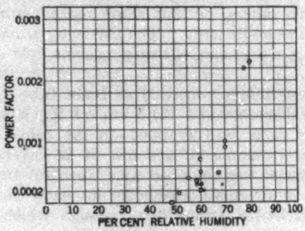

Fig. 8—Power Factor of Air Capacitor as a Function of Relative Humidity

. Air temperature, 20 deg. cent.
° Air temperature, 25 deg. cent.
□ Air temperature, 32 deg. cent.
70 kv. 60 cycles applied to the capacitor

Incidentally, it may be recorded that at high relative humidities, say 70 per cent or 80 per cent, flashover of the capacitor may occur at very low values, as low as 0.7 normal flashover voltage.

No explanation is offered for the observed phenomena beyond a guess concerning charge carried on dust particles. A mixture of permanent gas and unsaturated water vapor was expected to behave as a permanent gas in an electric field. It is believed that the only difference between such a mixture and the dielectric in the capacitor is the probable presence of dust in the capacitor.

### CONCLUSIONS

It is believed that dielectric power loss along two 10-ft. lengths of cable, as arranged for dielectric power-loss measurement in the usual way, has been measured by a thermal method with the accuracy expected from the apparatus employed; *i. e.,* with a probable error not over two per cent. This measurement is at a power factor near 0.003. That the usual electrical measurement of dielectric power loss indicates slightly higher losses, the difference being of the order of magnitude of dynamometer wattmeter reading error, may be either accidental or associated with a small loss concentrated at the end of the measured length, in the ⅜-in. spacing between the measuring section and the guard sections, indicated on the dynamometer wattmeter but missed by the thermal scheme. In either case, it is considered that negligible loss in the air capacitor used with the dynamometer wattmeter is demonstrated, provided that care is taken to keep the relative humidity below 50 per cent in the capacitor. Present practise with this capacitor is the maintenance of relative humidity below 40 per cent.

The thermal method used seems sufficiently simple, accurate, and independent of usual dielectric power-loss measurements, that its occasional use as a check in any laboratory making careful measurements of dielectric power loss is warranted.

# Residual Air and Moisture in Impregnated Paper Insulation—II

BY J. B. WHITEHEAD,[1] W. B. KOUWENHOVEN,[2] and F. HAMBURGER,[3] Jr.
Fellow, A. I. E. E. Member, A. I. E. E. Associate, A. I. E. E.

***Synopsis.****—The paper describes further experiments on the drying and impregnating processes of impregnated paper insulation for high-voltage cables. Conclusions are reached as to the relative advantages of drying at atmospheric pressure and under vacuum. The qualities of the product are discussed from the standpoint of conductivity, dielectric absorption, and power factor.*

*The influence of electric stress on impregnated paper and the progressive change in power factor under stress are studied in accelerated overvoltage tests. Evidence is presented as to the nature of certain interesting types of progressive change of power factor in their relation to the amount of residual air.*

* * * * *

## INTRODUCTION

In an earlier paper[4] we have described a series of studies of the influence of residual air and moisture in impregnated paper insulation, such as used in high-voltage cables. Briefly, the method used was to prepare samples in groups of three, to dry them in accordance with a standard program, to impregnate them at different values of absolute air pressure, and to study the resulting influence on the power factor-voltage curves. This gave information as to the influence of residual air. Separate studies were made of the dielectric absorption and residual conductivity of the paper before and after impregnation for different states of initial dryness. These studies, in conjunction with the resulting power factor-voltage curves, gave information as to the influence of moisture.

One of the conspicuous results of these studies was the relatively small importance of the air pressure, at which impregnation took place, on the resulting power factor-voltage curves. Between one and ten cm. Hg., absolute pressure of evacuation, there was little or no change in the shape of these curves. Moreover they were exceptionally good as compared with the curves of commercial cables, being perfectly flat, up to 300 volts per mil working stress, and for temperatures up to 50 deg. cent. It is only at impregnating pressures above 25 cm. Hg. that the typical rising break in the power factor-voltage curve begins to be evident.

Another result of interest is the relatively small importance of a variation in the moisture content on the shape of the power-factor curve. Moisture content is a relative term, and the foregoing statement refers to variation as regards moisture in a condition which must be described as fairly dry.

## COMPARISON OF DRYING PROCESSES

In view of these results it appeared desirable to study the relative importance of the different drying processes. The inspection of many factories in this country and abroad has shown an extremely wide variation in practise in this regard. The extremes noted were a preliminary drying process at atmospheric pressure, followed by six days under temperature and vacuum, on the one hand, and absence of all preliminary drying, immediate submersion in compound, and 24 hr. heating at reduced pressure on the other. It is obvious, therefore, that either some cables are much better than others, or that some manufacturers are wasting time and energy. The following studies were undertaken in the hopes of throwing some light on these questions:

Each test sample consisted of brass tube 2.54 cm. (1 in.) in diameter, and 121.9 cm. (4 ft.) long. The wood-pulp paper was wrapped on the tubes spirally in the usual manner to a depth of 25 layers. The finished sample was equipped with a central measuring electrode with guard electrode at each side. An electrically heated drying box, through which a slow draft of air is passed, permits drying at atmospheric pressure, and an electrically heated impregnating chamber permits an evacuation down to one mm. Hg., absolute air pressure, before the admission of the compound.

An electrically heated high-voltage test box with suitable electrostatic screening permits measurement of power factor and other alternating quantities, by means of the Schering bridge, up to stresses in the neighborhood of 300 volts per mil. Provision was also made for measuring dielectric absorption and conductivity up to 1500 volts at all stages of the several processes. For further details the earlier paper should be consulted.

In studies of this character it is important to know as closely as possible the state of the paper at the start and at all subsequent times. In drying by elevation of temperature at atmospheric pressure the final steady state of the paper depends on the temperature, the time, and the relative humidity of the atmosphere. Similar samples carried through the same drying process, but at different times, may have widely different residual moisture and electrical properties. It is obvious, therefore, that a standard temperature-

time program of drying will not result in uniform condition and properties for all samples.

Results presented in the earlier paper trace the behavior of cable paper as regards dielectric absorption and final conductivity, from the initial state when it contains about 10 per cent of moisture by weight, through a drying program which indicates clearly that for temperatures above 90 deg. cent. the conductivity, the dielectric absorption, and the power loss all increase with moisture content. C. Lubben[5] has shown an approximately uniform increase of dielectric absorption with moisture content up to about 5 per cent of moisture. The determination of the absolute amount of water in cable paper is difficult if not impossible, as it continues to give off moisture with increasing temperature, up to destruction. We have preferred therefore to use the conductivity of the paper as an indication of its condition as regards moisture content. The adoption of final conductivity as a standard for the condition of the paper had the advantage that it is a relatively simple matter to adjust the conductivity and hence the relative moisture content to any desired value.

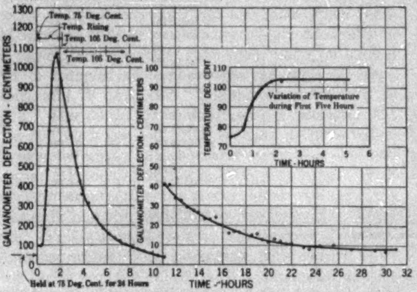

FIG. 1—TYPICAL DRYING CURVE OF UNIMPREGNATED PAPER

Variation of conductivity with time drying in presence of slow draft of air

As a standard condition for the paper we have taken the conductivity which results from a treatment of 105 deg. cent. for 72 hr. at atmospheric pressure in a drying box, through which there is a slow passage of air. In this process the paper reaches a steady state at the end of 48 hr. The change in the conductivity starting from the value of 75 deg. is shown in Fig. 1. The absorption characteristics are shown in Fig. 2. The final conductivity is $0.77 \times 10^{-10}$ mhos per cu. cm. The paper in this condition, therefore, is seen to be an excellent insulator, although possessing high dielectric absorption.

This program of drying and the resulting conditions as described represent the state of best preliminary condition of the paper found in any of our experiments. The current from the test electrode due to the above conductivity, and at 1500 volts, gives a deflection of 3 cm. on a precision galvanometer of sensitivity $2.23 \times 10^{-10}$ amperes. In what follows we shall use the galvanometer deflection directly as a measure of conductivity and moisture content.

In our studies of the relative importance of different periods of initial drying and impregnation, test samples were prepared in groups of three each, with final conductivities in the neighborhood of 30 cm., 60 cm., and 120 cm. galvanometer deflection respectively. The three samples in each group usually differ somewhat amongst themselves and it is therefore not possible to bring all three to the same value of conductivity. We have considered each group of three samples as a unit, treating and drying them together so that the final average values of conductivity are close to the figures mentioned. Specimens having the above characteristics were subjected in turn to evacuation processes represented by 5 cm., 2 cm., 1 cm., and 2 mm. Hg. absolute pressure. Throughout this program the final conductivity at the end of 24 hr. was in general taken as a basis of comparison. Three other groups were also included in this program of tests. No one of these received any preliminary drying and all therefore contained in the neighborhood of eight per cent to ten per cent of moisture. Two of these groups Nos. 28 and 29 were placed immediately in the evacuating chamber and the pressure reduced to 2 mm. Hg., the temperature being held at 105 deg. cent. and the conductivities observed at the end of 12 and 24 hr., respectively. The third group No. 36 was placed immediately in the impregnating chamber, without preliminary drying and the chamber immediately filled with compound. The pressure was reduced to 3 mm. Hg. and the temperature adjusted to 105 deg. cent. and both maintained constant for 24 hr.

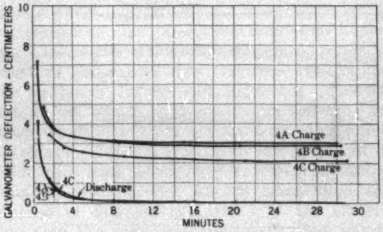

FIG. 2—CHARGE AND DISCHARGE CURVES

evacuation; column 3 the conductivity in cm. galvanometer deflection, the two figures indicating the extremes in the three samples of the respective group; and column 4 the average value of conductivity of the group. Column 5 gives the duration of exposure to the vacuum and column 6 and 7 the conductivities at the ends of the intervals given on column 5. The general arrangement of the table is such as to show continually decreasing values of initial conductivity as shown in column 4, at each pressure of evacuation. Groups 28 and 29, shown at the bottom of the table, receive no preliminary drying and were placed immediately in the evacuating chamber and the pressure reduced to 3 mm. No measurement was made of their initial conductivity and their initial state is described simply as "wet." Group No. 36 was placed in the impregnating compound without any preliminary drying or evacuation. The figures for the initial and final conductivity therefore have no significance in relation to the figures given in Table I. The properties of this group are best understood by a consideration of the power factor–voltage curves. These are shown in Fig. 3 and discussed in a later paragraph.

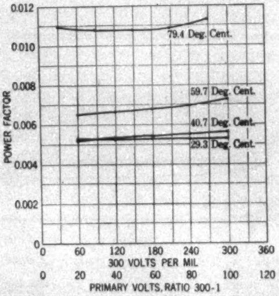

Fig. 3—Power Factor—Voltage Curves

Specimens 36A, 36B, 36C. Conductor diameter = 1.0 in. Insulation = 0.10 in. wall. No preliminary drying

The results as given in Table I indicate that for samples having different values of initial conductivity, corresponding to 30, 60, and 120 cm. galvanometer deflection at 1500 volts, when subjected to 105 deg. cent. and vacua represented by 5 cm., 2 cm., and 1 cm. Hg., absolute air pressure, it is not possible under any length of time to reach the same degree of dryness represented by a sample heated for 48 hr. in a slow draft of air at the same temperature and at atmospheric pressure. The standard value of final conductivity referred to above is approached more and more closely, however, the lower the evacuating pressure.

Evacuation pressures in the neighborhood of 2 or 3 mm. Hg. are necessary if the sample is to be brought down to the standard value of conductivity. Moreover at this pressure and 105 deg. cent. temperature this final conductivity may be reached in 24 hr. regardless of the initial state of the specimen; *i. e.*, a specimen that has had no preliminary drying, and contains therefore in the neighborhood of ten per cent of moisture, may be completely dried in 24 hr. at 2 mm. Hg. and 105 deg. cent. (sets Nos. 28 and 29). Special provision should be made in this case, however, for taking care of the large amount of moisture liberated in the evacuating system.

A freshly prepared sample (group No. 36) having no preliminary drying placed immediately into the impregnating compound at temperature 105 deg. cent. and pressure reduced to 3 mm. Hg. and maintained for a total duration of 24 hr., yields surprisingly good results. The power factor–voltage runs were made on such a series of samples at temperatures 29 deg., 40 deg., 59 deg., and 79 deg. cent. The curves are shown in Fig. 3. The curve at 29 deg. cent. is perfectly flat up to 300 volts per mil, thus showing a curve which compares favorably with our best specimens obtained by other methods of drying and impregnation. With increasing temperature the power factor–voltage curve shows only a slight tendency to rise over the voltage range. This is at variance with the behavior of our best specimens, which with increasing temperature show power factor–voltage curves with a maximum at relatively low stress and thereafter decreasing values of power factor. See Fig. 4. This effect is entirely absent even at 79 deg. cent., in the specimen now under consideration, the power factor–voltage curve at that temperature being approximately flat at low stresses, rising somewhat toward higher stresses. On the whole, however, the curves of set No. 36 show no marked internal ionization and compare well with well dried specimens. The absorption curves taken at 1500 volts continuous potential showed no marked differences.

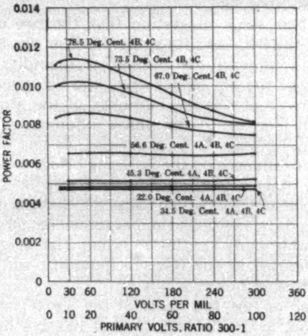

Fig. 4—Power Factor—Voltage Curves

Specimens 4A, 4B, 4C in parallel. Conductor diameter = 1 in. Insulation = 0.10 in. wall. Impregnated at 2 mm. pressure. Conductivity in dried state = 4A—3.40 cm.; 4B—3.45 cm.; 4C—2.55 cm.

It is interesting to speculate as to an explanation of the differences between the curves of Figs. 3 and 4. In the foregoing paper we have traced the intimate relation which exists in impregnated paper between the dielectric loss and the dielectric absorption, as observed under continuous potentials. Moreover, there is much evidence and we are convinced that the phenomenon of dielectric absorption, not only in impregnated paper, but in many other forms of insulation, arises in the conductivity, in the case of paper of the impregnating compound, and in other materials in local paths, due to moisture or other impurities. Now the conductivity of the best grades of insulating liquids is due to the presence of mobile ions in limited numbers. These ions may be swept out at relatively low voltage acting for long periods of time, and more rapidly at higher voltages. In the case of the best impregnated paper, as illustrated in Fig. 4, we may therefore explain the decrease in power factor with increasing potential gradient at the higher temperatures as follows: At the higher temperatures the ions are more mobile and with increasing voltage gradient they are swept out of the field more and more rapidly with consequent reduction in conductivity. At the same time the out-of-phase or charging component of the current increases with the potential gradient, the two effects combining to cause a falling value of power factor with increasing potential gradient. In the case of the curves shown in Fig. 4 relatively moist paper is immediately immersed in the compound. The drying and evacuating under compound leaves some of the moisture in the oil. This has the effect of greatly increasing the number of ions present in the oil and probably in slowing up their mobility. The result is, that with increasing potential gradient conductivity and capacity remain approximately constant, resulting in an almost flat power-factor curve.

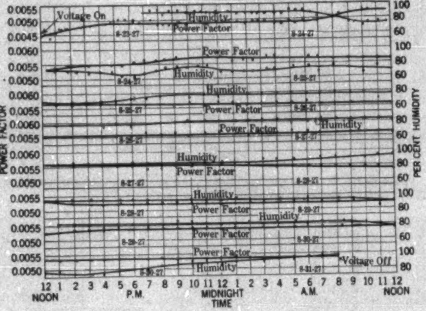

Fig. 5—Variation of Power Factor with Time

Cable specimens 33A, 33B, 33C in parallel. With 12,000 volts, a-c., 60 cycles applied continuously—40 deg. cent.

It is interesting to note that at low temperatures these samples which were dried and impregnated at the same time and with a total time duration of only 24 hr., show power-factor curves comparing very favorably with those of samples, dried, evacuated, and impregnated in separate stages over considerably longer periods of time. At the higher temperatures values of power factor reached are not seriously high. This raises the question whether this short and convenient method of drying results in a poor cable. There is undoubtedly an indication of danger in the rising power factor–voltage curve at higher temperatures. Thoroughly dried and evacuated insulation shows a markedly drooping curve. We attribute the rising curve in the present case to a greatly increased conductivity of the compound, due to moisture. Life tests now in preparation may bring out serious results of these differences.

Charge and discharge curves, 1500 volts d-c. Before and after specimens were held at 12,000 volts for 190 hr., 60 cycles,—24.2 deg. cent.

FIG. 6—SPECIMENS 33A, 33B, 33C IN PARALLEL. EVACUATED AND IMPREGNATED AT 2 MM.

### CHANGE OF POWER FACTOR WITH TIME

Those accustomed to measuring the power factor of cables and impregnated paper in general have frequently noted that the power factor changes with the time. For the most part, these reported changes are gradual but in a few cases very rapid changes have been reported, as for example, an absolute change of 40 per cent within a few minutes. In our own experiments we have noted changes of a few per cent in observed values from day to day, but for the most part they have not been sufficiently great to require special study nor to affect the general conclusions we have drawn from our studies. The most serious changes of this type we have noted are associated with poorly impregnated specimens at high temperatures. In these cases ascending and descending power factor-voltage curves are separated and variations with time have been noted. Following are the results of further studies in this direction:

One group of samples (No. 33) was dried at 105 deg. cent. and an absolute pressure of 2 mm. Hg. for 24 hr. and then impregnated at approximately this pressure. Power factor–voltage curves were then taken at room temperature (see Fig. 6) and then the temperature was raised to 40 deg. cent. and held constant. The power factor–voltage curve was again taken and all specimens were short circuited and grounded for four hr. The samples were then subjected to 12,000 volts, corresponding to a gradient of 120 volts per mil, continuously for 190 hr. The variation of the power factor during that interval is shown on the accompanying curve No. 5, which shows also the variation of the relative humidity. The value of power factor could be read at intervals as short as two min. When the values were changing frequent observations were made, and always at intervals of at least one hr. It will be noted that during the entire run the maximum variation in power factor was from 0.0045 at the start to 0.0057 on the night of August 24. The final steady value of power factor was 0.0052. The greater part of this difference arises in the first four hr. after the application of voltage, the value reached at this period being 0.0049. The total change during the whole run succeeding this was therefore seen to be relatively small, *i. e.*, 0.0049 to 0.0052.

There was some suggestion that the rise of power factor on the 24th and its gradual fall on the 28th was due to the influence of the relative humidity on the constants of the air condenser of the Schering bridge. If an increase of relative humidity of the atmosphere caused an increase in the phase difference of the air condenser, by leakage or otherwise, as has been suggested, the influence on the Schering bridge would be to lower the observed value of power factor of the specimen. Such an effect would cause the changes indicated in the two days mentioned and as shown on curve No. 5. On the other hand on the 30th and 31st there was a steady increase in the relative humidity without apparent effect on power factor.

In order to test the value of the above mentioned assumption, as to the influence of relative humidity, we made a few preliminary experiments on a small enclosed air condenser in which the humidity of the atmosphere could be controlled. We found that above 80 per cent relative humidity there was an effect of the type mentioned; namely, the conductivity and so the phase difference of the air condenser increased to a value other than zero. Experiments are still in progress to see whether this effect is due to a leakage over the insulation or to some other cause. In the meantime the results obtained have enabled us to correct the few power factor readings which we have found it necessary to take at values of relative humidity above 80 per cent.

At the end of the above mentioned run on group

No. 33, the voltage was interrupted for intervals of one min., five min., and for 30 min., and the power factor measured at the end of each interval. No change in power factor from value 0.0052, at which the original run ended, was observed. In a 20 hr. period without voltage, however, there was a recovery in power factor from 0.00510 to 0.00477. All of these measurements were at temperature of 40 deg. cent. The temperature was then allowed to fall and another power factor-voltage curve taken at room temperature, see Fig. 6. This checked very closely with the original observations indicating that the several series of voltage cycles, the sustained run at 120 volts per mil, and the successive interruptions have not affected the insulation in any permanent way. We conclude from these observations that with well impregnated insulation no sharp and no permanent changes in power factor are to be looked for within a voltage run of 190 hr. at 120 volts per mil.

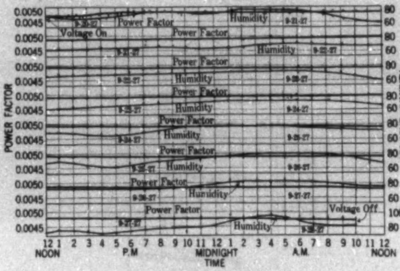

FIG. 7—VARIATION OF POWER FACTOR WITH TIME

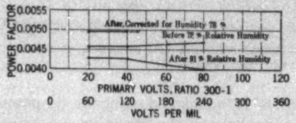
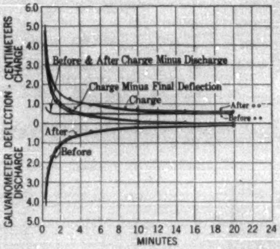
Cable specimens 34A, 34B, 34C in parallel with 12,000 volts, a-c., 60 cycles applied continuously—40 deg. cent.

Measurements were also made of the dielectric absorption and final conductivity at 1500 volts and at atmospheric pressure, before and after the time run described above. The results of these tests are shown in Fig. 6. An interesting feature in these curves is that there was a slight increase in the absorption and a very large decrease (about 60 per cent) in the final conductivity. There is no apparent explanation for this decrease in conductivity. We have noticed this effect in connection with other specimens and it seems to be associated with an initial and temporary condition of the oil following impregnation. It has no apparent influence on power factor observations, as these are determined in large measure by the absorption.

Similar studies as those described for group No. 33 were made with group No. 34, which were dried and evacuated at 2 mm. pressure, but impregnated at 15 cm. pressure. The purpose here was to study the possible influence of a greater proportion of residual air in causing time changes of power factor. The 190 hr. run at 120 volts per mil is shown in Fig. 7, which also gives the curve of changes in relative humidity. It will be noted that there was no abnormal change in power factor. In fact, the power factor remains remarkably constant, beginning and ending at the same value 0.0047, and with a maximum elevation in the intervening period to 0.00495. There is, however, an elevation in the relative humidity above 90 per cent towards the end of the run. Making the corrections on the observed value of power factor in the manner already referred to, the final value of the power factor becomes 0.00495, as indicated in Fig. 8. We therefore found in this group of specimens, as also in group No. 33, a slight increase in the value of power factor as a result of the time run under voltage. There is therefore no evidence here of any marked differences between the specimens impregnated at 2 mm. and at 15 cm. The power factor-voltage curves compared with those for similar specimens reported in the earlier paper are much the same as to both type and values.



Power factor—Voltage curves. Before and after specimens were held at 12,000 volts, 60 cycles for 190 hr.—40.3 deg. cent.



Charge and discharge curves, 1500 volts, d-c. Before and after specimens were held at 12,000 volts, 60 cycles for 190 hr.—40.2 deg. cent.

FIG. 8—SPECIMENS 34A, 34B, 34C IN PARALLEL. EVACUATED AT 3 MM.—IMPREGNATED AT 15 CM.

The absorption showed no marked changes following the 190 hr. run (see Fig. 8).

Group No. 35 was dried and evacuated at 2 mm. pressure and impregnated at 30 cm. pressure. Impregnation at this pressure was known to result in a rising power factor-voltage curve. This group was subjected to the same type of run of 190 hr., at 120 volts per mil and at 40 deg. cent. The results in the power factor are indicated in Fig. 9, which again shows an initial period with rise from 0.0056 to 0.0058 over the first hour and thereafter a slow decrease to a very uniform and steady condition, the testing ending with the value 0.0053, slightly below that at which it started. There were no abnormal elevations of humidity as indicated by the humidity curve, also plotted in Fig. 9.

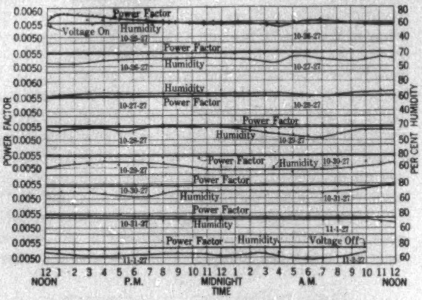


FIG. 9—VARIATION OF POWER FACTOR WITH TIME

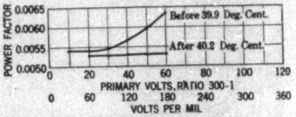
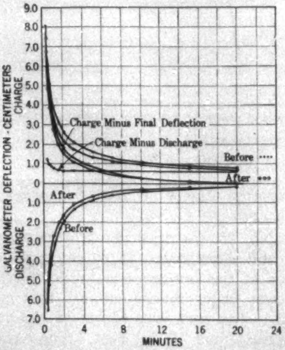
Cable specimens 35A, 35B, 35C in parallel with 12,000 volts, a-c., 60 cycles applied continuously

Of particular interest, however, in connection with group No. 35 is the marked change in the power factor-voltage curve between the beginning and the end of this time run. These curves are shown in Fig. 10, and it will be seen that at the beginning there is evidence of pronounced internal ionization, which however seems to disappear as the result of prolonged application of voltage. In the same figure will be found the absorption curves for the beginning and end of the test, indicating a decrease of absorption corresponding to the decreases observed in power factor.



Power factor—Voltage curves. Before and after specimens were held at 12,000 volts, 60 cycles for 190 hr.—39.9-40.2 deg. cent.



Charge and discharge curves, 1500 volts, d-c. Before and after specimens were held at 12,000 volts, 60 cycles for 190 hr.—deg. cent.

FIG. 10—SPECIMENS 35A, 35B, 35C IN PARALLEL. EVACUATED AT 3 MM. IMPREGNATED AT 30 CM.

Two principal explanations suggest themselves for the improvement in the ionization curve of group No. 35 just described. The first of these is a possible improvement in the impregnation due to the fact that in the time runs the specimens are immersed in the compound in which they are impregnated. Although at ordinary temperature and up to 50 deg. this compound is fairly stiff and does not flow readily, it appears possible that there may be a slow change in the degree of impregnation of the samples, over so long a time as 200 hr. The other possible explanation is an influence of the continued application of voltage.

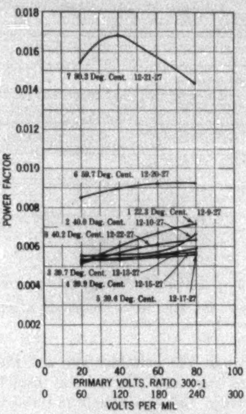


FIG. 11—SPECIMENS 37A, 37B, 37C

Impregnated at 30 cm. Hg. with dried influence of submersion in compound. Curves taken in order 1-8 on dates shown. Voltage applied only during measurements

In order to test the relative importance of these two suggestions an additional group of specimens, group No. 37, was dried and impregnated at 30 cm., giving a group in all respects similar to group No. 35. After the usual process of impregnation, the power factor-voltage curve was taken at atmospheric temperature. The resulting curve is shown as No. 1 in Fig. 11. We then raised the temperature to 40 deg. cent. and power factor-voltage curve No. 2 in Fig. 11 was observed. Voltage was then removed from the specimens and they were allowed to stand in the compound at 40 deg. cent. for a period of 190 hr., voltage being applied only long enough to obtain the power-factor curves Nos. 3, 4, and 5 of Fig. 11. It will be noted therefore that there was an apparent steady improvement in the direction of flattening of the power-factor curve, during this period. At the end of the period, however, the specimens were taken through a temperature cycle up to 80 deg. and on returning to 40 deg. it was seen that the power-factor curve again takes on the ascending shape approximating that of the initial condition. We conclude from these observations that while there is some evidence of improvement of the insulation when standing idle in the compound, it is not a permanent improvement and that after an elevation of temperature the insulation again takes on its original undesirable characteristics.

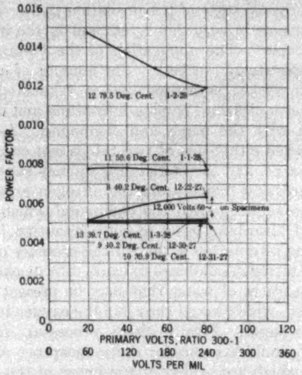

Fig. 12—Specimens 37A, 37B, 37C

Impregnated at 30 cm. Hg. well dried. Influence of continuous application of voltage. Curves taken in order 8-13 on dates shown. 12,000 volts, 60 cycles on specimens for 190 hr. between curves 8-9, at other times voltage on only during measurements

In order to study the influence of the prolonged application of voltage, the same set of samples, No. 37, was next subjected to a run of 190 hr. at 120 volts per mil, at a temperature of 40 deg. cent. The results are shown in Fig. 12, in which curve No. 8 of Fig. 11 is repeated, and the succeeding curves numbered in the order in which they were taken. It will be noted that the 190 hr. run results in a greatly improved, that is, a perfectly horizontal power-factor curve at the end of the run, that a succeeding temperature cycle gives power-factor curves at higher temperatures, similar to those of well impregnated samples, although perhaps a little higher, and that on return to the original temperature of 40 deg. cent. the power-factor curve retains its horizontal position.

The results of the foregoing tests are quite surprising. Although the samples were thoroughly dried they were impregnated at a pressure of 30 cm. Hg. and under these conditions tests, within a period shortly after preparation of specimens, have indicated very undesirable characteristics from the standpoint of ionization. Apparently therefore the insulation is greatly improved by exposure for 190 hr. to a stress of 120 volts per mil. On completion of the foregoing tests all three of the specimens of group No. 37 were dismantled and the paper carefully unwound. It was found that all three of them present all the outward evidences of thorough impregnation, that is to say, the color was uniform throughout and there was entire absence of air pockets or layers. However, on unwrapping samples No. 37 it was found that the paper was noticably drier and more crinkly than that removed from our best type of samples well impregnated at lower pressures. The paper seemed to be drier and actually to have less compound in it.

In order to test these questions still further similar runs were made on a group of samples, No. 42, which contained still more air. In the cases of all the foregoing groups, which were dried before impregnation, this drying was accomplished by subjecting them to a temperature of 105 deg. cent. and absolute pressure, 2 mm. Hg. for a period of 24 hr. They were then allowed to stand for two hr. at the air pressure at which impregnation was to take place, *e. g.*, 30 cm. Hg. in the case of group No. 37. Group No. 42 was dried at 105 deg. cent. in a slow draft of air at atmospheric pressure as already described. The final moisture content as indicated by the conductivity was the same as in group No. 37. They were then impregnated at a pressure of 30 cm. This group, No. 42, was never subjected to an atmospheric pressure lower than 30 cm. It therefore contained more air than the foregoing group No. 37, although both were impregnated at the same pressure. Fig. 13 gives the result of the 190 hr. run at 120 volts per mil and Fig. 14 shows the dielectric absorption and the power factor–voltage curves, both before and after the time run, for group No. 42. The

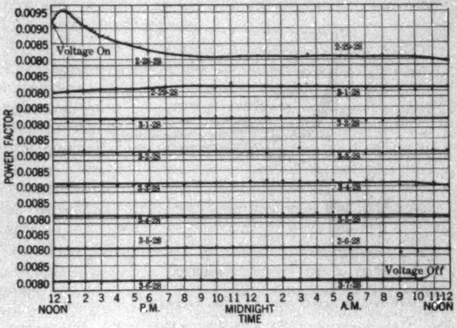

Fig. 13—Variation of Power Factor with Time

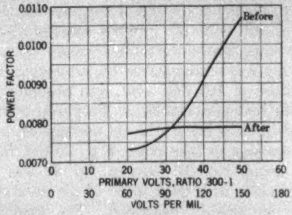
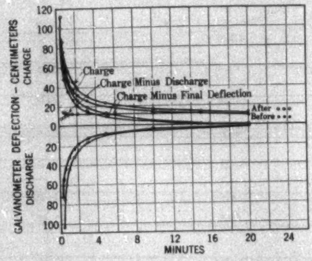
Cable specimens 42A, 42B, 42C in parallel with 12,000 volts, a-c., 60 cycles applied continuously—40 deg. cent interesting things to note about these curves are the slight initial rise of power factor at the beginning of the time run, which however, was followed by a noticeably greater decrease during the succeeding eight hr., and the marked changes of the power factor–voltage curve at the end of the time run. The changes in the dielectric absorption are in accord with the changes in power factor. Of these changes the most interesting is the marked improvement in the power factor–voltage curve, as the result of the time run. Before the run this curve rose sharply above 20 volts per mil, indicating copious internal ionization as expected, in view of the large amount of air known to be entrained in the insulation. After the time run, however, this curve became almost flat, lying slightly higher at lower voltage stresses, but rising very little over the remaining voltage range. It appears, therefore, that the improvement noted in connection with group No. 37, resulting from a prolonged run at high voltage, is still more sharply emphasized in the case of group No. 42.



Power factor—Voltage curves. Before and after specimens were held at 12,000 volts, 60 cycles for 190 hr.—40 deg. cent.



Charge and discharge curves, 1500 volts, d-c. Before and after specimens were held at 12,000 volts, 60 cycles for 190 hr.—40 deg. cent.

FIG. 14—SPECIMENS 42A, 42B, 42C IN PARALLEL. EVACUATED AND IMPREGNATED AT 30 CM.

We conclude, therefore, that well dried paper when impregnated at 30 cm. Hg., absolute pressure, has in its initial condition a considerable amount of air and reveals a sharply rising power factor–voltage curve indicating considerable internal ionization. In its earlier stages if left to itself there are progressive changes in the internal condition, as to impregnation, but no permanent change in the undesirable ionization characteristic. On application of voltage there is a steady improvement in the condition of the insulation as regards its ionization characteristic, as indicated by the power factor–voltage curves, and after approximately 200 hr. the insulation reaches an apparently excellent condition with little or no evidence of internal ionization.

In explanation of the foregoing we offer the following: In the original state of the insulation the air exists for the most part in very thin layers and in the interstices of the paper. The application of the voltage ionizes these separate air pockets. The amount of oxygen in each air pocket is limited and is exhausted by the process of ionization, passing into ozone and into combination with the paper and compound. As regards the nitrogen either one of two things can occur. If it is left native, and therefore inert, we may suppose that with increasing temperature the nitrogen expands and goes into solution with the compound which has the power of absorbing gases in some quantity. A more promising alternative is that in the presence of ionization the nitrogen combines to cause nitrous oxides, and with the traces of water that may be present to form nitric acid, which would thus join the oxygen in attacking the paper. Finally these processes, singly or together would account for a disappearance of the air pockets, which are evident if specimens of this type are dismantled in the early stages of their life. The rate of decrease of this disappearance of air is indicated by the curve of Fig. 13 in which it is seen to occur during the first seven or eight hr. after the application of voltage. This explanation would also account for the relatively dry and crinkly appearance of the paper at the end of the run under high stress, and which was very evident in groups No. 37 and No. 42. We attribute this condition to the formation of small amounts of wax or other solid decomposition product which has been frequently noted in connection with over-stressed cable insulation.

The evidence of the foregoing results indicates clearly that the continued application of voltage may result in a marked improvement in the power factor characteristics of impregnated paper, through a consumption or absorption of entrained air, as a result of the process of ionization. An original ionization characteristic is not necessarily a permanent property of this type of insulation.

Another feature of interest in connection with the time runs, described above, is the initial rise in power factor during the first hour or two after the application of voltage. We attribute this rise to the energy liberated within the body of the insulation as the result of dielectric loss. The rise stops as soon as the automatic temperature control equipment readjusts itself to the new rate of energy supplied. Following this initial rise it will be noted that in the cases of samples

No. 35 and No. 42 there is a steady decrease in power factor below the initial value. This decrease is most sharply marked in group No. 42. In the case of these two samples we attribute this steady decrease to the consumption of the entrained air and a consequent lessening of the amount of ionization leading to a decrease in energy loss. The effect is more marked in the case of group No. 42, because that group was known to contain more air originally. One of the authors has already recorded[6] experiments showing the limited amount of oxidation and the gradual change in the nature of the discharge in a thin ionized layer of air, when the layer is completely sealed.

In the earlier paper we have emphasized the close relationship between dielectric absorption and dielectric loss or power factor. The results of the present studies are quite consistent in this regard. In all cases of power-factor changes during the time runs described above, corresponding changes may be observed in the dielectric absorption. The absorption curves, however, were all taken at 1500 continuous volts, which gives a stress far below the alternating values used. Absorption curves for this type of insulation at stresses comparable in value to those of alternating service and tests, are badly needed. In connection with the absorption curves we have plotted the difference between the currents of charge and discharge. This difference shows the irreversible absorption current which is seen to have a considerable value in all the above cases and to rise sharply toward the short time interval, after the application of voltage. This indicates not only the complex character of dielectric absorption as it occurs in impregnated paper, but also that the irreversible absorption current accounts for a substantial portion of the total loss. It is our hope to be able to extend our studies in this direction in the near future.

These studies were carried out in the School of Engineering of The Johns Hopkins University at the request and with the support of the Subcommittee on Impregnated Paper Insulated Cable Research, of the National Electric Light Association, D. W. Roper, Chairman. For the continued interest and hearty cooperation of the members of the committee the authors extend their grateful acknowledgment.

## CONCLUSIONS

Taken in conjunction with the earlier paper our present results would seem to indicate the following:

1. For the drying of cable paper before impregnation, preliminary drying before vacuum treatment is unnecessary, except perhaps as a convenient method of driving off a large part of the water always found in cable paper.

2. Drying at reduced air pressure is very much more rapid than drying in the open, for the same drying temperature. At a drying temperature of 105 deg. cent. at atmospheric pressure, and in a steady draft of air, a steady condition of the paper as regards dryness is reached only after from two to three days. The same condition can be reached if dried at 105 deg. cent. in a vacuum of from two to five mm. Hg. absolute pressure, in from 12 to 24 hr. It is not possible, however, to reach this same condition of dryness over any length of time if the evacuation pressures are above 5 mm. Hg. It is probable that a continuous replacement of water vapor, by dry air in the vacuum chamber, would alter this conclusion. The great value of the draft of air, however, when drying at atmospheric pressure is evident. Higher values of the temperature result in further improvement as regards dryness and conductivity.

Initially undried and unevacuated paper placed immediately in the impregnating chamber and then subjected to heating to 105 deg. cent. and evacuation pressure of 3 mm. Hg. for 24 hr., results in an insulation having remarkably good properties. At temperatures up to 40 deg. or 50 deg. the power factor–voltage curves are flat and of value of the same order of magnitude as those pertaining to specimens that are far more carefully dried. In the upper range of temperatures the power-factor curves have abnormal shapes, although they do not show values unduly high.

4. For thoroughly dried paper impregnated at 105 deg. cent. and pressures of 2 mm., 15 cm., and 30 cm. there are no sharp changes in power factor following abrupt changes of voltage.

5. Prolonged runs under voltage cause no appreciable changes in the properties of thoroughly dried and impregnated insulation (dried at 2 mm. Hg. and impregnated up to 15 cm. Hg.). For insulation impregnated at higher pressures there is a pronounced improvement as a result of the continued application of voltage. We attribute this to the slow consumption of the entrained air in ionization, and its combination with the compound, with resulting decrease in ionization losses.

6. The improvement in power factor noted in the foregoing paragraph is accompanied by a noticeable drying or stiffening of the paper. This we attribute to the production of solid decomposition products of the oil. We thus have the suggestion that the generation of "x-wax," or similar product, is associated with a decrease in power factor. Whether this would continue through long periods is a question for further study.

7. Poorly impregnated cable insulation may show excellent power-factor curves indicating low ionization for temperatures up to 40 deg. or 50 deg. cent. and yet not have permanent characteristics. Examples are group No. 36, impregnated without preliminary drying and showing the curves of Fig. 3, and the several curves around 40 deg. of group No. 37. In such cases a temperature cycle may result in a marked change of characteristics. At higher temperatures there are

---

[6] Jl. A. I. E. E., December 1923, p. 1297.

often marked differences from the characteristics of insulation which is thoroughly dried and impregnated.

8. A general survey of these and foregoing studies indicates the relative unimportance of air pressure of impregnation within a fairly wide range say up to 15 cm., and even up to 30 cm., if the paper is vacuum dried. Excellent power factor-voltage curves may be found throughout this range. We conclude therefore that the sharply rising curves and rapid changes in power factor, often noticed in commercial cables are due to relatively large and extended areas of entrapped air or gases, resulting either from imperfect impregnation, distortion in handling, or temperature expansion of lead sheath.

---

## Discussion

### DIELECTRICS AND INSULATION

(Scott, Bousman, Benedict, Whitehead, Kouwenhoven, and Hamburger)

Baltimore, Md., April 17, 1928

**W. F. Davidson:** In the paper by Scott, Bousman, and Benedict mention is made of some tests that were conducted to determine the influence on the values obtained of controlling the potential of the guard circuits and in this particular case they found it quite satisfactory to connect the guard circuit to ground. However, in some cases this would not give satisfactory results. I think it is well to caution people working with such measurements to see that they check their own individual circuits.

As a case where serious errors were introduced, I might mention one in which we made a considerable number of measurements at voltages corresponding to a stress of about 250 to 300 volts per mil. In this case we found harmonics in the guard circuit which introduced serious errors in measurement unless they were carried off.

It would seem that the information with regard to the air-capacitor performance (Fig. 7) would be considerably more valuable if stated in terms of stress instead of total voltage applied.

**Donald Bratt:** The consideration of calorimetric methods in dielectric research on high-voltage lead-covered cables confronts us with several interesting problems. The temperature rise on the surface of the cable sheath due to dielectric power loss is significant not only for its average value when taken over a considerable length of cable, but also for its fluctuations over this length.

All our present electrical methods for measuring dielectric power will give only the average value. Now it is well known that a cable which ultimately fails on a high-voltage test gradually develops a "hot spot" at the place of failure long before this failure occurs. It does not seem impossible, therefore, that a study of the steady-state temperature rise whether it be due to dielectric loss alone, to copper loss alone, or to both, could be used as a measure of the *homogeneity* of the insulation.

Let us first take the case of dielectric loss. Assume that a long cable sample subject to high voltage has developed a steady surface temperature rise $\theta = f(x)$ where $f(x)$ is a temperature which may vary over the length of the cable, as measured say from its midpoint ($x = 0$.) In particular, let $f(x) = \theta_1 + \theta_2 E^{-mx_2}$ meaning that in addition to the normal temperature rise $\theta_1$ there adds an amount $\theta_2 e^{-mx_2}$ due to a typical hot spot at $x = 0$ (see Fig. 1 herewith). The question now arises: What conclusions can be drawn from such a temperature curve in regard to the specific loss? It is evident that the sheath must exercise some equalizing influence, so that the variation in losses is more pronounced than exhibited by the surface temperature. Considering the longitudinal heat conduction in the cable as well as the heat dissipation from the cable surface, an expression involving maximum and minimum specific loss is easily derived:

$$\frac{W_{max} - W_{min}}{W_{min}} = \frac{\theta_2}{\theta_1}\left(1 + \frac{2\,m\,\lambda\,a}{T\,S}\right)$$

$W_{max}$ occurs at $x = 0$

$W_{min}$ occurs at $x = \pm\infty$ (meaning *far* from $x = 0$)

$T$ = heat dissipation constant.

$S$ = sheath circumference

$\lambda\,a$ = longitudinal heat conductivity.

Substituting ordinary values for those constants, and assuming $m$ to be $10^{-3}$ per cm² (this would correspond to a temperature decreasing to ½ of its maximum value for $x = \pm 25$ cm.) we obtain

$$\frac{2\,m\,\lambda\,a}{T\,S} = 2.5\,a\,b\,t.$$

and the range of variation is seen to be 1 + 2.5 = 3.5 times as severe as that which would be indicated by the surface temperature.

In view of the recent discussions of thermal breakdown, it would seem to be of great interest to determine the greatest value of $m$ conformal with steady-state performance, as this maximum value undoubtedly reflects the quality of the insulation.

Considering further the question of homogeneity of insulation and the likelihood of a hot spot developing in a region of (let us say) poor heat conductivity, it might be desirable to have a factory test whereby such regions could be detected without even cutting the cable and preparing a sample. Observation of surface temperature rise when the cable is heated,

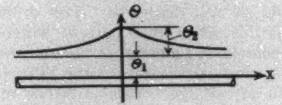


Fig. 1

a. by current in the copper conductor
b. by current in the sheath

leads us immediately to the following conclusions:

1. If the same temperature-rise curve is observed *irrespective* of whether the cable is heated in the copper or the sheath, then the variation in temperature rise must be ascribed to conditions *on the surface*, and the insulation is homogeneous.

2. If the temperature-rise curve differs materially depending on the mode of heating, its variation must, partially or altogether, be ascribed to heterogeneous insulation.

An expression for the equalizing effect of the sheath, on the assumption of constant copper temperature and negligible drop through insulation as compared to drop from surface to ambient air, can easily be derived. We get

$$\theta = \theta_0 + \frac{Q}{t\,A}\left[1 + \frac{E}{\left(1 + \frac{W^2\,h\,\lambda}{T}\right)}\text{Sin. } W\,x\right]$$

where the thermal conductivity of the insulation has been assumed to fluctuate around a mean value with a small amplitude $E$ and a period $x$ where $x = \frac{2\pi}{W}$

The masking effect of the sheath thus manifests itself by cutting the amplitude $E$ down to $\frac{E}{\left(1 + \frac{W^2\,h\,\lambda}{T}\right)}$

Otherwise $\theta$ = temperature at any value $x$

$\theta_0$ = ambient temperature
$T$ = heat dissipation constant
$A$ = total surface of cable sheath
$Q$ = total heat developed in copper
$h$ = thickness of cable sheath
$\lambda$ = lead heat conductivity.

For an ordinary cable, the factor $\frac{W^2 h \lambda}{T}$ would come out about 0.1 so that the equalizing effect of the sheath is not very serious for fluctuations of a reasonably long period. For such fluctuations, therefore, the temperature-rise curve gives a close picture of the variation in thermal conductivity along the cable.

**H. L. Curtis:** In these two papers we have had presented to us some statements regarding air condensers. In one of them the authors have drawn the conclusion that when the humidity is above 40 or 50 per cent there is a loss in the air condenser. The authors of the other paper, I believe, do not get any loss until the humidity is about 80 per cent. In neither case do I think the data are sufficient so that we can judge whether there is a loss in the air itself or whether it is a question of a loss in the solid insulators which support the plates of these air condensers.

**T. S. Taylor:** I should like to ask a question in regard to the construction of the condenser; in particular, is the insulation supporting the plates at all in the field set up by the condenser? Again, is any attempt made to differentiate the factors relative to the losses in the insulation constituting the supports and the conduction losses over the insulating materials?

My experience in measuring power factor at extremely low values such as those of quartz, particularly at high frequencies, has led me to believe that the ordinary type of condenser does not enable us to detect the differences between the components that go to make up the total loss in the condenser. At the present time we have not been able to come to any conclusions as to the distribution of the losses among the various components.

**Alexander Nyman:** I had an opportunity a few years ago to make tests very similar to those described in Dr. Whitehead's paper in connection with impregnated paper condensers, and I am glad to be able to corroborate these tests. Our results were very similar.

In the first place we have to distinguish four factors in connection with impregnated paper condensers. There are the breakdown voltage, the life, the leakage, and the dielectric losses. The leakage is the thing that is most affected by humidity and moreover, by temperature, and the temperature is one factor, I believe, that is not brought out in this paper. We made a number of condensers and put them on long-time tests and observed the relation of leakage current, temperature, and humidity at the same time. We found that the effect of the temperature during the summer months, when the temperature goes up to 80 or 90 deg., was quite marked—more so than humidity. Now those were condensers which were completely impregnated in wax, and yet it seems that the moisture was able to penetrate through the layers of wax and affect the leakage.

Now as regards drying it is exactly as the paper states, you don't have to extract the moisture previous to impregnation. Impregnation, especially if carried out under a vacuum, will extract the moisture. Of course it is a different proposition in manufacturing. In manufacturing it may pay to extract the moisture before impregnation because there may be quite a large amount of moisture trapped and it would prolong the impregnation process too much. But as an actual improvement in the final quality, previous drying is not an important factor.

I should like to say something about what is in my opinion the most important quality in condensers, and presumably cables as well—that is, the life. Of course tests on leakage current and on dielectric losses probably have some bearing on the life, but the relation between these values and the life of the insulating material is not at all evident, and I believe that a much more satisfactory way to predict the life of this material would be to determine by tests—probably very extensive tests—some kind of a law which would connect the life of a condenser with the potential applied to it. Both cable manufacturers and condenser manufacturers have conducted tests of accelerated life at higher than normal voltage, and two or three different laws have been suggested. Cable companies, particularly the British companies, have worked out one kind of logarithmic law to determine the life of a cable at excess voltage. Other laws are slightly different, just the usual power laws. In other words, the life of a condenser will be inversely proportional to a certain power of the voltage. Now these laws will give different results and it is hard to say which is the correct law. This is really a question of great practical importance to both manufacturer and user of every impregnated material. Such material is similar to incandescent lamps or many other electric products which have a definite life; what the life is going to be depends on how severe a service you subject it to.

If you produce a condenser, say, and want to know what is the rating you are going to apply to it, you have to know what the life of the condenser will be before you can decide at what voltage you are going to rate it; in order to determine the life it is either a case of conducting tests for ten years or so, or else applying some law that has to be found by actual tests to be correct. I should like to bring this point to the attention of the investigators.

**A. W. Gray:** I have been much impressed with the fact that apparently no satisfactory explanation has yet been offered to account for the so-called anomalous properties of dielectrics. The various phenomena described by Dr. Whitehead recalled to mind work that had been done in Berlin 25 years ago. I believe that this work gives a clue to a very simple explanation not only of these so-called anomalies, but even of specific inductive capacity.

The work that I refer to was not done upon materials used for electrical insulation, or with any idea at all of elucidating dielectric phenomena; it was done for the purpose of investigating the formation of ozone by the silent electrical discharge in the Siemens ozone generator. This apparatus is essentially a condenser with a composite dielectric consisting of two glass walls separated by a layer of oxygen or of air.

If such a condenser is charged it behaves much as any other condenser behaves until the intensity of the electric field becomes sufficient to break down the insulation of the gas layer and cause a sudden passage of electrons across this layer from one glass plate to the other. This passage is accompanied by a flash of light and by a sudden increase in the charge of the condenser. In addition, there is some comparatively slow passage of electricity from one side of the gas layer to the other by surface leakage along the bounding glass walls. When the composite condenser is discharged by connecting its electrodes together, there is another sudden passage of electrons across the gas layer, in the reverse direction; but this passage ceases when the potential gradient falls to a certain minimum. After this, the discharge continues slowly because of internal leakage around the gas layer. If the electrodes of the condenser are disconnected while the leakage progresses, residual charges on them become evident when they are again connected together.

Every substance, no matter how pure it may be, or how good an insulator it may be, must contain minute spaces distributed among portions that insulate more or less perfectly. These spaces may be bubbles or intermolecular spaces or interatomic spaces or even intra-atomic spaces. The insulating portions may be pictured as forming baffles that intercept electrons shot through the material by the action of an electric field. The conduction current that persists after the field has been established may be pictured as consisting of electrons that succeed in penetrating the baffles and of electrons that are passed on by some procedure analogous to elastic impact. When the substance forms the dielectric of a condenser, the normal currents of charge and discharge may be thought of as arising mainly, if not wholly, from sudden passages of electrons across spaces bounded by layers of baffles. Leakage around these spaces could account for the phenomena associated with dielectric absorption. Such leakage could result from even traces of conducting substances dispersed throughout the dielectric. Since the capacity of such a composite condenser must depend upon the internal structure of its dielectric, it follows that, in general, different substances should be expected to exhibit different specific inductive capacities.

This view conforms to all the essential requirements of Maxwell's theory of heterogeneous dielectrics. For Wagner's artificial assumption of conducting spheres imbedded within a pure dielectric medium without conductivity, it substitutes an internal structure known to exist in every substance. I have not yet learned of any dielectric phenomenon—normal or anomalous—that does not seem to be a natural consequence of actions similar to those observable on a larger scale in a Siemens ozone generator.

An ozone generator can be made to yield information for quantitatively testing deductions from the hypothesis that I have just outlined. For example, electricity passed through the gas layer does work in converting oxygen into ozone and ozone into oxygen. By suitable construction of the generator, internal surface leakage can be rendered negligible, so that the quantity of electricity passed through the gas can be determined from electrical measurements that are fairly easy to carry out. When oxygen flowed through such a generator fast enough to eliminate the de-ozonizing action of the silent electrical discharge, I found, among other things bearing upon dielectric behavior, that the mass of ozone produced was directly proportional to both the quantity of electricity that passed as conduction current through the gas and the difference of potential applied to the electrodes, that is to say, directly proportional to the electrical work done upon the gas. Energy similarly expended upon air occluded within the insulation of a power cable means power-factor loss as well as production of ozone, which should be more active than ordinary oxygen in causing deterioration of the dielectric.

Those interested can look up my original papers.[1] They will find there accounts of such things as the effect of water vapor in the gas and the effect of reducing the suddenness of charge and discharge by inserting a high resistance in the electric path, as well as a description of a method that I devised for using a ballistic galvanometer to measure a single charge, or discharge, while the modified Siemens ozone generator was alternately charged and discharged rapidly at various potentials ranging up to over 12,000 volts.

**J. B. Whitehead:** There has been a number of suggestions from time to time that dielectric absorption arises in the absence of homogeneity of the dielectric itself, and I understand that the suggestion of Dr. Gray is that air spaces through the combination that they offer of leakage paths and also the presence of gaseous ionization, will lead to the ordinary phenomena of dielectric absorption as we know it.

**T. F. Peterson:** One phase of the second paper is particularly interesting to me and I should like to go into it in some detail. To me the results expressed in Figs. 13 and 14 are very striking and indeed, at first thought, seemingly peculiar. They are obtained on what we might consider, in the light of the work done here, poorly impregnated paper, which contains a considerably greater percentage of air than the ordinary samples tested. The explanation offered for the improvement in the power-factor—voltage curve of Fig. 14 seems to be along the right line but probably could be somewhat amplified. The authors have recognized that this rejuvenation of the cable, as we might call it, due to voltage applications, exists, and have accounted for it by saying that the air has either disappeared or has gone into combination with the oil, or something equivalent has taken place. In any event, they claim that it is not due to the entrance of compound from the outside. I do not think that the tests made would warrant forming such a conclusion.

At the Winter Convention of the A. I. E. E. we had a paper by some Russian experimenters on *The Influence of Internal Vacua and Ionization on the Life of Paper Insulated High-Tension Cables*,[2] and in a discussion of it I derived a theoretical power-factor—voltage curve which was very similar to the ones obtained by these experimenters and others. Curve *A B C D* shown herewith in Fig. 2 is typical. At low voltages we have a range of constant power factor. Then, with increase of voltage, a certain stress is reached at which there is an increase in power factor, the curve finally reaching a point where it bends down and becomes negatively sloping. The point at which the increase in power factor takes place is dependent on the thickness of the films at the conductor and also the pressure of the gas. As the voltage increases there is a spreading of the volume of gas in ionization until some point is reached where all spaces are ionized, and then there is a dropping off of the power factor. The curves obtained by plotting the equations which I have derived have been checked up fairly well by experiment.

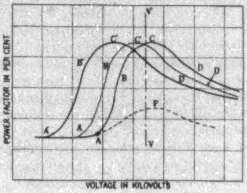

Fig. 2

The point I wish to emphasize is this. Point *A* depends on the pressure of the gas since the value of the stress at which the ionization takes place is proportional to the pressure. Now as the air is absorbed by the compound or is combined in some way with the paper, the pressure will undoubtedly be reduced, and I think to explain fully the characteristics obtained in this paper, we have to consider this. As the pressure changes curve *A B C D* will be moved over to *A′ B′ C′ D′* and we could have a series of curves depending on internal pressures, the lower the pressure the farther left will the curve be.

Now the power factors obtained and plotted in Fig. 13 are for constant voltages. If, with a line plotted through *V V′*, a constant voltage, we consider the power-factor curves moving over with speed proportional to the decrease in pressure and then plot power factor at voltage *V V′* against time we would have a curve such as that given in Fig. 13. This appears to be a partial explanation for the improvement in power factor observed.

In Fig. 14 we have two power-factor curves; one is obtained before any voltage has been applied and is of the characteristic type. It is quite conceivable, due to the slow movement of the compound in cable, that after this application of voltage, the pressure is considerably less than atmospheric. This, in itself, may result in power factor decrease. It may also promote movement of compound into cable which will also assist in this direction. The point at which curve *A B C D* begins to rise is dependent, as I said before, on the pressure in voids and also on the thickness of them. The slope of this curve is dependent on the percentage of these spaces throughout the cable. When the pressure of the gas within the cable is reduced during this test, as the air is combined with the oil, presumably the volume or the percentage volume will remain the same if no compound enters the cable. If compound does enter the cable the characteristics will change and instead of getting curve *A B C D* one would probably get a flatter curve, such as *A P*. In any event, either the reduction in pressure during the test or the entrance of compounds would tend to give us this flat characteristic which is the second one obtained in Fig. 14. Which is the predominating influence is difficult to say because we do not know whether the rate of the reduction of pressure due to the combination of air with the compound is greater than the rate of entrance of the compound. We should have to have some idea of the relative values of those two changes with time before we could say one way or another which was the important influence. I do think, however, that either one can explain the characteristics in some measure.

**S. J. Rosch**: I believe, after reading this paper, that in presenting the data it has been the intention of the authors to attempt to shed light on some of the obscure fundamentals of dielectric phenomena as occurring in a lead-covered impregnated-paper cable. The cable model as constructed by the authors was an ideal one since the physical relationships between the conductor, insulation, and outer sheath remained constant throughout the experiment, whereas in actual practise the insulated cable receives a number of bending cycles during the various operations before lead covering, and after lead covering during the installation in the ducts, thereby introducing various voids in the insulation proper and between the outer layers of insulation and lead sheath.

Furthermore, for the reasons just mentioned, the electrical characteristics of the cable on the reel in the factory may be entirely different from those obtainable on the cable after pulling through the ducts. Then again, during the entire time when these tests were conducted on the model cable, the latter was completely submerged under oil, a condition entirely foreign to cables as ordinarily manufactured and tested, and only comparable to the conditions accompanying the testing and operation of the oil-filled 132-kv. cables.

However, the data presented in this paper should be of paramount importance to the cable manufacturer, as they indicate an acme of perfection in characteristics not obtainable at present on a commercial scale it is true, but as a desirable goal for the manufacturer to strive to attain in the cables of the future.

I believe, however, that the value of the paper would have been enhanced considerably, if some of the measurements, such as those used to obtain power-factor—voltage curves, could have been continued at temperatures below 29 deg. cent., such as 0 deg. cent.,—10 deg. cent., and — 18 deg. cent., as representing conditions actually met with underground in Chicago and other parts of the country. It would really be of interest to note how the ideal cable would have behaved under these temperatures and whether the compound used would have contracted under the cooling, thereby perhaps causing void formation and producing a different form of ionization curve.

If this research is to be continued, I would suggest that the experiment be repeated but this time using a flexible stranded conductor, the tests being made before and after bending the cable, so as to study effects approaching as nearly as possible those encountered in actual cable practise. I suggest this merely with the thought that a consideration of these parallel data, obtained by the same experimenters, might throw some real additional light on a phase of electrical engineering still woefully obscure.

**G. M. J. Mackay:** Dr. Whitehead's paper emphasizes the fact that in drying cable, applied vacuum simply increases the rate of moisture removal because of the more rapid diffusion of water vapor into the lower ambient pressures. There is no mysterious "pulling out" effect produced by a vacuum pump.

However, it is not quite clear from the paper how the various pressures were maintained. For instance, when a pressure of 5 cm. is specified in Table I, does this mean that the pump was kept running and a constant rate of leak into the apparatus maintained, or that the pump was shut off after a pressure of 5 cm. had been reached? In the latter case, of course, water vapor would not be so thoroughly removed, if at all, and the dryness of the paper would be entirely independent of the pressure of gases other than water vapor itself. Perhaps the relative rate of leak may explain the unexpected improvement found at pressures of 3 mm. Most vacuum pumps do not completely eliminate water vapor from a system because of compression of the vapor to liquid which re-evaporates into the system. Drying agents therefore should be used as near as possible to the material to be dried. The lower the pressure, the more rapid will be the absorption of water vapor by the drier, so that this also may be a factor in the increased rate found at 3 mm.

We have investigated the effect of vacuum on both electrical characteristics and endurance by treating in the laboratory 20-ft. lengths of cable with 9/32-in. insulation, subjecting them to vacuum treatments with pressures varying from 25 mm. to 0.1 mm. and in some instances using liquid air to condense the water vapor. No appreciable difference was found either in characteristics or in life, although these experiments being made with ordinary cable, the effect of such variables may have been masked by the greater effect of voids.

Cable equal in quality to that prepared by the usual methods has also been made by submersion of undried lengths in oil although we have used for this purpose somewhat higher temperatures than those applied by Dr. Whitehead.

We feel that it is decidedly unsafe, however, to carry the conclusion (No. 8) of "the relative unimportance of air pressure of impregnation within a fairly wide range, say up to 15 cm." to the manufacture of long lengths of cable with insulation ¾ in. thick. With the relatively short specimens and thin insulation used by Dr. Whitehead in his experiments comparatively little gas may be trapped. But with a length of cable having insulation ¾ in. thick, impregnation at even 1-cm. pressure may result in undesirable gas pockets. Under the worst condition with compound admitted suddenly and advancing from both ends and the circumference simultaneously, the residual gas at 1/76 atmosphere may be compressed into a single large bubble, which if none escaped, would mean a pocket at atmospheric pressure of 1 ft. in length for every 76 ft. of cable. Either special methods to eliminate this residual gas, or the use of the best vacuum obtainble seems necessary if internal ionization is to be eliminated.

As a matter of fact, oil-filled cable for 132,000 volts is exhausted at pressures always less than 5 mm. and usually below 2 mm.

**W. A. Del Mar:** This work of Dr. Whitehead and his associates is, in my opinion, very valuable and useful to all of us interested in this problem of cable manufacture, because it tells us the properties of a type of cable which must be avoided at all hazards, namely, the perfectly oil-filled cable.

It was my hope and expectation both that the authors would make a perfect cable, not an air-free one, in order that we might have a standard by which we could measure our less perfect commercial products, and that they would ascertain the effect of variations in process upon the quality of the dielectric produced.

The air-free cables made by the authors will probably have zero value from an operating standpoint, if lead-sheathed. If tested under operating conditions of temperature and pressure cycles, I surmise that they will make a very poor record, because the sheath will stretch permanently at high temperatures and high vacua will form at low temperatures, permitting destructive ionization to bring the cables to an untimely end.

The thoughtless will deduce from these tests that the lower the ionization and the higher the dielectric strength, the better the cable This does not follow. In my opinion present-day cables have gone beyond the optimum operating values of these quantities.

The work of Dr. Whitehead and his associates, moreover, seems to come to an end at the point where the really big problems of the manufacturer begin. The big problems of manufacture in impregnation relate principally to dealing with large masses of material and with time limitations. That is to say, one has to consider the movement of air and the movement of oil in large masses, and in the case of the experimental work in this paper those two elements of mass and time are not taken into account. The authors may say, of course, "We stop where you manufacturers should take up the problem," and perhaps that is right, but there are several places in the paper where one would not get that impression. For instance, on the first page occurs the sentence: "The following studies were undertaken in the hopes of throwing some light on these questions," that is to say, the reconciling of two very widely different methods of manufacturing cable. I do not see that experiments on 4-ft. lengths of cable, with the quantities of oil used, throw any light on the relative merits of manufacturing processes.

In order to understand the drying, evacuating, and impregnating processes, the rates of flow of moisture, air, and oil, the masses of water, air, oil, and paper, the nature of the available equipment, and the time commercially available, are the main factors which must be studied. Of course, the authors have not considered these factors, but they have written their paper as if the factors in question are negligible. For instance, it is stated that it is "only at impregnating pressures about 25 cm. Hg. that the typical rising break in the power-factor—voltage curve begins to be evident." This value of 25 cm. is given as a constant, whereas in reality it is only an accidental value depending on the capacity of the particular vacuum pump used in the experiments. In the impregnation process used in these experiments there is a race between the rising oil and escaping air. The authors say that their experiments indicate the air wins the race if the vacuum is better than 25 cm., but they should say that the air wins if the oil does not rise faster than 96 ft. per day, (or whatever the rate may have been) the connection between this rate and the 25-cm. vacuum being dependent on the capacity of the vacuum pump which is sucking up the oil.

I am puzzled by conclusion No.1, which states: "For the drying of cable paper before impregnation, preliminary drying before vacuum treatment is unnecessary, except perhaps as a convenient method of driving off a large part of the water always found in cable paper." Of course, that is the thing we are all trying to do.

No conclusions should be drawn from the experiment on the change of power factor with continued application of voltage until it is studied under more practical conditions, as it is probably a phenomenon peculiar to the test conditions and not to cable in general. If the cable is tested in long lengths, pressure equalization will take so much time that local dielectric heating may cause pressure instead of increased air spaces, thereby giving an entirely different ionization-time curve than obtained on tests of an open 4-ft. length.

I should like to make sure, in places such as Fig. 10, where it says, "impregnated at 30 cm." that that means absolute pressure.

In conclusion I would couple my praise of the excellence of the laboratory work with a caution against drawing conclusions therefrom without giving full consideration to large-scale manufacturing conditions and the modifying effect of temperature and pressure cycles in service.

**W. S. Clark:** The information I am giving comes from the Commonwealth Edison Company. About six months ago they installed some lengths of 132-kv. cable under pressure. They also installed a Schering bridge so that they could make power-factor measurements. There were three or four samples of cable there and I don't know which sample is which except the sample which is oil-filled and which is quite easily distinguished because it is the only one that has shown no change in its electrical characteristics since installation. It comes nearer to what we want as a cable and for cable insulation than anything we have yet had. On the broad question of oil-filled cable—you might say that all cable is oil-filled—but what I mean is cable with reservoirs of oil under pressure,—the use of the ordinary type of cable where the static pressure varies with the temperature of the cable, will have to be worked out on an economical basis. For some voltages it will be advantageous to use an oil-filled cable. For some lower voltages it will be economically better to use the other. But the oil-filled cable so far has done what it was expected to do. In the operating circuits, entirely apart from the circuit I have spoken of, there have been no electrical failures since last June in Chicago and last August in New York, and that includes joints.

**F. M. Clark:** Any discussion concerning the drying of cellulose materials for electrical purposes must define what is meant by the term "dry." In Pittsfield we have found that a sheet of paper may be placed in a 100-deg. cent. oven and dried to a constant weight in approximately 24 hr. If impregnated in this condition the power-factor characteristic will be similar to that described by the authors, yet we do not consider such material dry. Up to this point apparently all that has been done is to remove a large part of the absorbed moisture. To remove more water and to obtain what we term a dry sheet suitable for high-voltage electrical apparatus such as capacitors we have found that a somewhat prolonged vacuum treatment is essential. The actual weight of water removed from the insulation during this stage is not great. The effect on the dielectric characteristics of the insulation, however, is marked, the insulation resistance rising to a high value and power factor dropping well below 0.25 per cent. We believe that in this last stage of the drying process we remove completely all traces of absorbed water together with some water of hydration from the cellulose molecule.

Figs. 3 and 4 illustrate what is termed by the authors as satisfactory behaviour. The effect of voltage on the power factor is absent at low temperature but becomes somewhat more pronounced at higher temperatures. An inspection of Fig. 3 shows that for a constant voltage stress the power-factor—temperature relation varies with the stress applied. At 60 volts per mil, for example, it shows a minimum power factor at approximately 40 deg. cent., whereas at 300 volts per mil the power factor rises rather sharply from room temperature. With Fig. 4, however, the characteristic "V"-shaped curve is obtained at all voltage stresses. It is a characteristic of what we term a well treated dielectric to possess a "V"-shaped power-factor—temperature curve with its minimum value at approximately 35 deg. cent. and a power factor at 50-60 deg. cent which is approximately equal to that shown by the insulation at 25 deg. cent. The authors' curve of Figs. 3 and 4 shows comparatively high power factor at 55-60 deg. cent.

We have in many cases noted a temporary rise in power factor during the early stages of an over-voltage run and have credited it to about the same causes as have the authors—the dissipation of entrapped air or residual traces of water vapor. However, we have not been convinced that ionization is necessary to remove such residual gases. It has been our experience that, even without voltage, gas bubbles trapped in an oil dielectric will disappear in a manner which indicates that the gas is being removed by the process of solution.

The authors in conclusion No. 1 see no reason for a preliminary air brake except as a convenient method for driving off a large part of the water present. As far as I know no one has advocated a preliminary air brake for any other reason. Their conclusion No. 2 states that it is impossible to dry insulation with a pressure of higher than 5 mm. of mercury; yet it is possible to dry in air at atmospheric pressure. It is hard to reconcile such statements unless with the experiments made under 5 mm. of pressure the drying box was tightly sealed in order to hold the pressure constant at this value. Such a static condition cannot be compared with the ordinary conditions present in vacuum treatment where leakage introduces a steady current of air through the treating tank. It is, of course, impossible to dry insulation completely in a "dead" space where a water-vapor equilibrium is soon established between the insulation and the surrounding space.

**G. B. Shanklin:** In regard to the ionization characteristics in the paper by Dr. Whitehead and his associates, from the experience we have had I would attribute the greater part of the unexpected results to the fact that their cable samples were in a bath of compound. We have found that that is the ideal condition; if we could build cable and keep it in a bath of compound we could ask for nothing more. I do not mean, in making this statement, to give the impression that their work is not of extreme value. A fresh point of view and a different way of making the tests is always helpful, but the conditions we have in the actual manufacture of cable, in large vacuum chambers, on large reels, leading those cables and preventing void formation, are really very different from the type of research work which they have conducted. As Mr. Clark pointed out, the liquid oil-filled cable will approach the condition of their research work more closely than a cable filled with heavy compound.

**D. W. Roper:** In Fig. 13 of the paper it will be noted that there is an increase in the power factor with time during the first few minutes following the application of the test voltage. This is the only curve which shows this peculiarity and this curve was taken from a cable sample that was purposely made of poor quality. Professor E. B. Paine, in some investigations that he is making at the University of Illinois, obtained a similar curve from a sample of cable known to be of poor quality that was sent to him for testing purposes. We have recently in Chicago made a life test on a sample of cable showing a similar curve, that is, an increase in the power factor in the first few minutes after the application of the voltage. This test resulted in an unexpectedly short life for the sample of cable as indicated by the other quality tests which had been made in advance of the life test. It is suggested that this point be given careful attention as there is some possibility of this increase in power factor during the first few minutes after the application of the voltage being a more accurate indication of the life of the cable than the actual value of the power factor itself.

**R. W. Atkinson:** I think we have had the first presentation of absolute measurements of the dielectric-loss characteristics of the air condenser, which itself has previously been taken as an absolute standard of capacity and power factor. Now, we have measurements on the air condenser checked against standards even more fundamental. Certain limitations have been shown, in respect to humidity, for the air condenser but it is shown further that, under the usual conditions of use, the air condenser is correctly used as it has been used and is, within the limits stated, an exceedingly satisfactory unit for the purpose.

In the earlier discussions of the paper on residual air and moisture it has been truly said that the measurements are under conditions which are different from those in the factory. It is, however, perhaps this very fact that gives the paper its greatest value. There are already numerous data about the characteristics of cable made under factory conditions. Here we have a set of data about cable made under very carefully controlled conditions, and with these conditions varied in a controlled manner. The application of these conditions, as has been pointed out, is not a matter for an amateur, but it is proper to emphasize that the very real value of this study is due to its uniqueness.

**R. J. Wiseman:** I am going to say only a few words with respect to the cable manufacturer's point of view on the paper of Dr. Whitehead and his associates. I am in agreement with what others have said in regard to the limitations of cable manufacture. There are some points I should like to have considered, not only from the electrical point of view but also from the physical.

Under Conclusion 4, they say "for thoroughly dried paper," etc. We must define "thoroughly dried paper." We can dry paper to the point where it is destroyed and get very good electrical values. However, cables are made to operate for many years. Shall we stop at 0.1 per cent moisture or shall we stop at 0.02 per cent moisture or even go to 0.01 per cent? That is something the cable manufacturer must consider at all times. 0.03 per cent moisture is very readily noticed on the paper by its brittleness. A 0.1 per cent gives good electrical characteristics and longer life. However, the power factor is slightly higher than what we get for 0.03 per cent moisture. Which do we want? From a cable manufacturer's point of view I would say 0.1 per cent if you want to get life out of your cable.

Referring to Figs. 5 and 13, the variation of power factor with time which Mr. Roper has referred to as showing that power factor will vary with time, really is not very great. It is a pretty flat curve from a commercial point of view, only changing 0.05 per cent. It is a good idea to make the ionization test at the beginning and end of a voltage test such as the 24-hr. test we are now making. If the power factor does not show a large increase it can be considered good cable.

With regard to Conclusion 8, I can hardly agree with the statement that:

"We conclude, therefore, that the sharply rising curves and rapid changes in power factor, often noticed in commercial cables, are due to relatively large and extended areas of entrapped air or gases resulting either from imperfect impregnation, distortion in handling, or temperature expansion of the lead sheath."

This may be entirely correct for the rapid changes in power factor but not for the sharply rising curve of power factor, particularly for the higher temperatures. This can be a function of the nature of the compound used. Some use rosin in the compound which gives a slightly increased power factor at higher temperatures, and even at the lower temperatures without rosin you can get a slightly changing power-factor curve. The curve is really a function of the kind of materials used.

**C. L. Kasson:** (by letter) In regard to the paper entitled *A Thermal Method of Standardizing Dielectric Power Loss Equipment*, I should like to point out that no comparison between the values obtained by the thermal and electric methods is correct unless the latter method makes use of electrical shields as well as guards.

Dielectric loss, as usually measured without shielding, includes the loss in the material and the loss in the adjacent air. Under some conditions the watt loss in the adjacent air may be greater than that in the material itself, thus introducing a large error into the unshielded measurements. This was shown in a paper by the writer entitled, *High-Voltage Measurements on Cables and Insulators*,[3] given at Pittsfield, Massachusetts, May 27, 1927, before the A. I. E. E. Regional Meeting.

In order to secure accurate comparisons between the thermal and electrical methods of measuring dielectric loss it will, therefore, be necessary that the electrical measurements be made using a system of complete shielding of the material, its connections, and measuring equipment.

**R. W. Chadbourn:** (communicated after adjournment) Messrs. Scott, Bousman, and Benedict have developed an ingenious and electrically simple method of checking watt-loss measurements on cables. It is unfortunate that the scheme involves such an elaborate set-up and so long a time period to produce steady conditions that its application would be very limited in the laboratory of an operating company—the very place where it might perhaps be of most value.

Considerable care must be taken that the sheath radiation is not affected by external air currents (this requires the use of an enclosed test box of large dimensions), the sheath temperatures must be carefully and accurately determined, and the test must be prolonged over a period of many hours, until the heat flow through the cable reaches a steady state. Because of these considerations, it seems to me that the scheme is chiefly of value to determine, once and for all, for a number of laboratories, the probable accuracy of any direct method of measurement, as with dynamometer wattmeter or the like, or to compare different dielectrics for cable use, where, perhaps, the most accurate possible knowledge of dielectric properties may be important.

---

[3] A. I. E. E. Trans., Vol. XLVI, 1927, p. 646.

It should be borne in mind that the measurement of dielectric loss in cables is not, in general, a precision test and that, except in rare cases, a high order of accuracy is not required nor expected. On installed cables, for instance, temperature variations along the cable introduce a variable of such magnitude that accuracy of more than 5 or 10 per cent is, in most cases, impossible. The important thing—in fact, all that can be hoped for—is to be able, by dielectric-loss measurements, to detect cables whose loss is so high that their condition may be definitely questioned, or which show, by a progressive change at given temperature conditions, evidence of gradual deterioration. There are now available, for installed cables, direct methods of measurement, the accuracy of which is known to be entirely satisfactory.

For laboratory measurements involving, in many cases, very short lengths of cables, the temperature variable can be readily eliminated, but this advantage is partly offset by greater difficulties of measurement, due to the smaller quantities measured and the errors introduced by end leakage. The latter can be practically eliminated by proper shielding and guarding, and at the present time portable wattmeters are available for use at very low power factors, of such range that measurements can be made at moderate voltages on lengths of cable as short as 25 or 50 ft., or with some types of cable, 10 ft., with sufficient accuracy for commercial comparisons.

**C. F. Hanson:** (communicated after adjournment) The authors of the paper on *Residual Air and Moisture in Impregnated Paper Insulation*, express a little surprise that Sample Group No. 36, which had no preliminary drying but was immersed in the impregnating oil while the applied paper insulation was at room condition in regard to moisture content, should possess good electrical characteristics. According to my experience, both from the point of view of laboratory performance and that of cable manufacture, I should be disposed to place my wager on Group No. 36 in preference to any of the other groups. I have found that the less the untreated paper is exposed to heat, the better will be the finished product, particularly in regard to dielectric strength. A decrease in the dielectric strength of the oil-impregnated paper due to exposure to heat prior to impregnation will be manifest long before any deterioration can be detected in the physical properties of the paper. If the burden is not too great, I suggest that the authors try to process a group by using a temperature of about 90 deg. cent. or even less in the preliminary and in the vacuum drying. Toward the end of the vacuum-drying period the temperature could be raised to 105 deg. cent. in order to facilitate impregnation when the oil is introduced and also to obtain an impregnating process comparable with that of the other groups.

The authors seem to prefer the power-factor—voltage gradient characteristics shown in Fig. 4 to those shown in Fig. 3. I have noted no data in this paper nor in the authors' previous paper to confirm this preference. I doubt whether anyone at the present time can produce laboratory data which would be conclusive. A laboratory test which will produce unqualified evidence as to the suitability of a cable for service performance is still lacking. Perhaps the best test available now is a long-time voltage test, usually referred to as a life test. I shall await with interest the results of the authors' life test on these various groups.

Below are given data of the power-factor—voltage gradient of two specimens of treated paper. Each specimen consisted of two disks of paper 30 cm. in diameter. These were dried in a current of air at 100 deg. cent. for 72 hr. This temperature was used because no means for vacuum drying were available. The paper was then immersed in the impregnating compound for 18 hr. at 100 deg. cent. under atmospheric pressure. The specimen was then assembled between brass disk electrodes immersed in a pan of the impregnating compound. An attempt was made to remove all visible bubbles of air. There may have been present small invisible air voids due to the method of impregnation. Both specimens were intended to be alike with the exception of the impregnating compound. Specimen A was impregnated with a high-specific-gravity and high-viscosity oil containing 15 per cent of rosin. Specimen B was treated with a mixture of petrolatum and a low-specific-gravity and low-viscosity oil and containing no rosin. It will be noted that specimen A has a power-factor characteristic at 79 deg. cent. similar to Group 36 in Fig. 3. Specimen B has a characteristic similar to that given in Fig. 4. The characteristics of both specimens at 23.5 deg. cent. were flat corresponding to Fig. 3 and Fig. 4.

| Volts per mil 60 cycles | Power factor at 79 deg. cent. Specimen A | Specimen B |
|---|---|---|
| 55 | 0.014 | 0.051 |
| 75 | 0.015 | 0.049 |
| 100 | 0.016 | 0.044 |
| 150 | 0.019 | 0.037 |
| 200 | 0.021 | 0.030 |
| 250 | 0.023 | 0.026 |
| 300 | 0.026 | 0.022 |
| 350 | 0.029 | 0.020 |

These specimens were subjected to a life test with the following results:

| Stress applied 60 cycles Volts per mil. | Temperature 80 deg. cent. Hours application of each stress Specimen A | Specimen B |
|---|---|---|
| 500 | 46 | 46 |
| 600 | 141 | 1.7 Failed |
| 720 | 10.5 Failed | |

The foregoing data are not conclusive by any means but they do suggest that the characteristic of Group No. 36 in Fig. 3 may possibly be preferred to that of Group No. 4 given in Fig. 4.

**W. N. Eddy:** (communicated after adjournment) It is suggested that the authors' first conclusion—that *atmospheric drying* before vacuum treatment is not necessary for the drying of cable paper—is not justified by the data given. Instead, the test results seem to indicate that *vacuum treatment* is not necessary for the drying of cable paper. On the second page of the paper the impression is given that a 3-cm. deflection was obtained after 48 hr. at 105 deg. cent. atmospheric pressure, which is practically as low as any of the deflections obtained in Table I with the aid of vacuum. Also, it should be remembered that pressures below 1 cm. are impractical for factory drying equipment. Table I and Fig. 1 indicate that 24 hr. at atmospheric pressure followed by 24 hr. at 1 cm. pressure (8-12 cm. deflection) did no more complete drying than 30 hr. at atmospheric pressure (8 cm. deflection).

The authors' tests indicate that the pressure and time of drying do not have a controlling influence on the quality of the insulation as shown by the power-factor—voltage curve—in other words, that the presence of some air and moisture in the insulation does not cause increased ionization. The writer is interested in a paper recently completed in which evidence is given that the presence of some air and moisture may actually decrease the ionization, confirming the authors flat power-factor—voltage curves on insulation saturated without previous heating or vacuum treatment.

The general lack of ionization shown by the authors' samples in spite of a wide range in drying conditions is further evidence that the principal cause of excessive ionization and premature failure in high-voltage cable insulation is the formation of contraction voids during cooling, both in the factory tanks and in service. The type of sample and conditions of impregnation and testing used by the authors would indicate that their insulation, as compared with actual high-voltage cable insulation, should be relatively free from such voids and, therefore, of superior quality. To mention another example of the great increase in quality caused by minimizing the formation of contraction voids, cable paper of low air resistance can be impregnated in sheet samples 21 mils thick without previous drying merely by 20-min. immersion in hot compound, so that it will withstand 15,700 volts (750 volts per mil) for 5000 hr. at room temperature. It is thus evident that when working with miniature samples of insulation it is often surprisingly difficult without lowering the saturation temperature to impregnate the insulation so that its quality is anything but satisfactory. As the most desirable method of improving the quality of cable insulation is to study its weaknesses, these characteristics of miniature samples constitute a serious objection to their use.

The authors find no material increase of power factor with time on voltage. Similar results have been obtained with 10-ft. cable samples on overvoltage in the laboratory at room temperature, with the cable ends unsealed. Fig. 3 herewith shows that 5000 hr. of 78 kv. 3-phase on a 3-conductor 33-kv. belted cable under these conditions resulted in a slight decrease in power factor with little change in curve slope. In view of the material increase of power factor often found on cable in service, the constancy of the power factor on the authors' samples and the cable samples suggests that neither test condition approximates actual service conditions closely enough to make the test entirely satisfactory as a criterion of cable insulation quality (its behavior in service). The principal disadvantage of the cable life test may be that the temperature is too uniform and the cable ends not sealed. In addition, the authors' tests have the disadvantage that the insulation is thin.

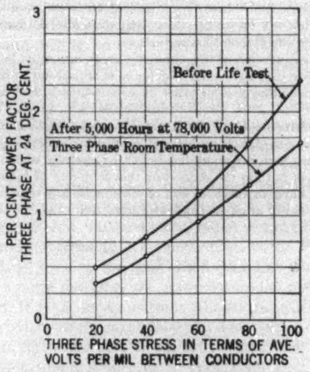

Fig 3.—Power Factor of Three Conductor Belted Cable 33,000 Volts Working Pressure

In general, it is believed that the authors' carefully made and interesting tests offer another example of the great difficulty in applying the conclusions of tests made under typical laboratory conditions to the manufacture and use of actual high-voltage cable insulation. It is becoming more apparent that what have been considered the most reliable indications of insulation quality available in the laboratory, the overvoltage life test and the power-factor—voltage curve, often fail to give a reliable indication of the relative behavior of the insulation in service, and that the principal difficulty is not the nature of the test but the conditions under which it is made. While the relatively constant-temperature, constant-pressure conditions of the laboratory tests tend to decrease the number of contraction voids, the variable-temperature, constant-volume conditions in service tend to increase the number of contraction voids.

**J. A. Scott and H. W. Bousman:** Mr. Davidson's caution about guard-circuit potential is timely. We do not think anyone should either ground his guard circuit or try to raise it to the proper potentials without due care. Particularly this is true with bridge circuits.

Referring to Fig. 7, the capacitor plate spacing is 11 cm.

Mr. Bratt's discussion of heat flow in a cable was very interesting and we hope he will find opportunity to amplify it. For example, we can find no indication that the surface temperature rise of a cable with a "hot spot" is typically a constant plus a normal frequency function, as given by him. There are considerable experimental difficulties with his proposed method for measuring thermal conductivity differences, a measurement which should precede a foot-by-foot comparison of heating test.

How long before failure does a "hot spot" develop?

We may as well admit to Dr. Curtis that so far as we can determine no one has made any conclusive experiments showing appreciably more conduction current in the electric field in moist clean air than in dry air. Our capacitor plates are supported by treated wood carefully kept out of the field, and we were able to repeat the measurements shown in Figs. 7 and 8 over a five-month period. We think there is a conduction current of the order of magnitude shown through the space between the plates. Dr. Kouwenhoven's work with filtered air is in the right direction.

**J. B. Whitehead:** Our point of view in planning the experiments described in the paper has been to isolate, as far as possible, the influence of air and of moisture on the performance of impregnated paper. In order to carry out this isolation it has been necessary to eliminate numerous other factors and conditions which necessarily are present in prevailing methods of manufacturing paper-insulated cables. In other words, we have been studying the fundamental properties of impregnated paper as influenced by air and moisture, quite without reference to the question whether or not it is possible to preserve and protect these properties completely in paper insulation, as assembled in a manufactured cable. The purpose of the investigation has been, therefore, to call attention to the principal differences which obtain between carefully controlled impregnated paper and impregnated paper as it actually functions when applied to a cable. We offer no excuse for this point of view; quite the contrary. We merely call attention to the fact that this is the method adopted in every scientific investigation which aims to uncover the causes of existing troubles. Naturally we shall be more than pleased if manufacturing methods can be improved so that the manufactured cable will approach more nearly the apparently desirable characteristics of some of our specimens.

We believe that many of the comments that have been made on our paper have been made without complete recognition of these facts. We by no means suggest that the processes we have followed in preparing our samples should be followed in manufacture, nor that any of them should be taken as a standard upon which a cable specification might be drawn. We do, however, believe that the relative differences to which we have called attention, among drying processes, impregnating processes, and resulting performance, are in general correct, and can be made use of as bases for changes in manufacturing methods.

For example, some of the comments of Messrs. Del Mar and Mackay have been directed towards possible variations in our results as affected by our methods of evacuating the impregnating chamber and holding the pressure constant. We believe that variations of the character mentioned are quite possible. We do not, however, believe that these variations would be very great. Moreover, as we have followed approximately the same program for all of our samples, we think that the variations so caused would not be great enough to influence the generality of our conclusions.

In direct reply to Dr. Mackay's question the pump was kept running during admission of compound. The rate of admission was adjusted so that the air pressure was maintained at the particular value under test. Departures from this occurred at the higher pressures owing to the limited capacity of the pump.

Answering Mr. Del Mar, the values of pressure are all given in terms of centimeters of mercury absolute pressure.

We have been much interested in Mr. Hanson's preference for the power-factor curves of Fig. 4, over those of Fig. 3, and his suggestion that any sustained heating of the paper, even at moderate temperatures, tends to lower its insulating value. We hope to be able to report in the future on the life tests on these and other types of sample suggested by his comments.

**W. B. Kouwenhoven:** Dr. Curtis has raised a very important question as in both the Schering-bridge and the dynamometer-wattmeter methods of measuring dielectric loss an air capacitor is used in connection with the measuring equipment. It is important for the accuracy of the results that this air capacitor be loss-free.

Scott, Bousman, and Benedict mention the effect of humidity on air capacitors in their paper. During the summer of 1927 troubles which I ascribe to humidity developed in our air capacitor at the Johns Hopkins University. Using continuous potential I made some tests on an air condenser fitted with guard rings and so constructed as to keep the dielectric out of the electrostatic field. The area of the main plate of this condenser is 2260 sq. cm. and the spacing between the plates 2.5 mm. Using this condenser and a continuous potential of 60 volts per mm., I obtained a conduction current of $3.74 \times 10^{-7}$ amperes, at 90 per cent relative humidity. This gives a value of power factor of 0.0008 for the air capacitor under alternating stress and the same voltage gradient as in the continuous-potential tests. It is interesting to note that this value is of the same order of magnitude as that Mr. Hamburger mentioned, as having found during life tests on cable specimens using another air condenser, and that E. S. Lee's results also agree quite closely with this value.

It is very important to know if air capacitors are free from loss or not, and we are studying that question now. We have constructed a special condenser using bakelite as a dielectric which is entirely enclosed and so arranged that air may be circulated through it, and at the same time the relative humidity of the air may be varied. To date all of the tests have been made with clean air (dust-free) and the humidity has been varied from about 40 to 95 per cent. Tests have been made at temperatures ranging from 23 deg. cent. (73 deg. fahr.) to 50 deg. cent. (121 deg. fahr.). In order to keep out the dust a cotton-wool plug is inserted in the air pipe. The value of the applied continuous potential has been varied from 10 to 60 volts per mm. No conduction has been detected with clean air, even at 60 volts per mm., and the following values of relative humidity, 92.5 per cent at 24 deg. cent., 91 per cent at 32 deg. cent., and 90 per cent at 39 deg. cent.

Atmospheric dust in Baltimore contains quite a large percentage of carbon particles, soot, bits of hair, fuzz, dried sputum, bits of dried grass and leaves, etc. One of the next steps in this investigation will be to introduce some dust into the humid air and note its effect upon the conduction.

In an investigation of this character great care must be taken to make sure that any conduction found is not caused by leakage over the insulation or some other unsuspected path, such as a bit of lint.

**J. B. Whitehead:** I think Dr. Kouwenhoven has not been quite definite in stating his belief in connection with the possible rise in power factor of an air condenser. Generally we haven't a great deal of faith in the suggestion that humidity of the atmosphere can have an effect, or can of itself cause any departure of the power factor of an air condenser from zero value.

# Improvements in Insulation for High-Voltage A-C. Generators

BY C. F. HILL[1]
Non-member

*Synopsis.—A discussion is given of the insulation problem in relation to increased size, rating, and voltages of turbo alternators and some results of experimental studies given showing the possibilities of improving the insulation to take care of such increases. Mention is made of the effects of high voltage testing and the use of hydrogen on the insulation problem and finally an explanation of a device for the elimination of corona formed around armature coils.*

* * * * *

THE present type of turbo alternator is the result of but little more than twenty years development but the changes in such machines have been frequent and impressive. The result is that machines are being built so much larger in size and power output than were considered possible a few years ago that we hesitate to predict the future or place a limit on their size. The same condition may become true for voltages as well. However, when we consider the advance in size and rating we are confronted with the fact that much of the change has been made possible by improvements in mechanical features, an outstanding example being the improvement in the method of removal of heat losses. It is true that the magnetic properties of the iron have been much improved and transposition of strands of conductors has helped to lessen eddy current losses, both being examples of electrical advancement, but as each step in the increase in output per unit was necessary, much of the problem was merely increasing the mechanical size. Yet if we could go back to the time when 5000 kw. was considered a large machine, we certainly would not have expected 150,000 kv-a. without almost revolutionary changes by the electrical engineer as well. The demand continues for larger and larger units, especially larger kw. output, and it is difficult to understand how much advance can be made without some improvement in the electrical features. Therefore, the electrical engineer must look for possible changes, in the magnetic circuit, in the generated currents and voltages, and in the insulation. It is the purpose of this paper to discuss the problem of the insulation engineer from the standpoint of increased voltages especially, with some discussion as to the effects of other developments on insulation, and by means of some experimental results to show some of the limits and possibilities which insulation may impose on further developments of turbine design.

## General Discussion

While further increase in voltage will determine the more difficult problem for the insulation engineer, he must keep in mind a number of other features which are to be expected in further turbine development. The mere increase in dimension increases the difficulty of insulating the conductor or coil and placing the coils into the slots in good condition. Armature coils are already of the order of 20 ft. in length in the straight part, and the difficulty of making and handling such coils must necessarily increase with length. Of more importance is the matter of temperature, heat dissipation, and efficiency. The insulation problem has always been tied in with that of temperature and heat removal in that the $I^2 R$ losses in the conductors must be conducted though the insulation and operating temperatures are actually determined by it. The present A. I. E. E. Standards permit, for armature windings, a maximum rise of 80 deg. based on a total temperature of 125 deg. and most large machines are now designed for an armature winding temperature rise of only 60 deg. Only a radical change in the nature and characteristics of insulating materials will permit designers to raise this limit of temperature rise appreciably.

A new development in the field of heat removal may make itself felt in the near future in the way of using lighter gases such as hydrogen for machine ventilation. A trial of this development is now under way and it will therefore be of interest to consider the relation of this method of ventilation to the insulation problem. The aim, of course, is to get increased output at the same temperature, and from this point of view, no effect will be expected on the insulation so far as temperature is concerned. Lighter gases are better conductors of heat and originally there was some hope that even the insulation itself might become a better heat conductor due to absorbed gases. As a matter of fact, an insulation that is good electrically, does not absorb gases to any extent and the only way in which it will be affected by the hydrogen atmosphere involves corona effects which will be mentioned later.

In the case of armature insulation, the development or changes over the past twenty years have been negligible. As a matter of fact, it can almost be said that the idea of arranging paper, mica, and a bond as we have them now, made possible the modern turbo generator. At first, voltages were relatively low and machines comparatively easy to insulate. But even as voltage increased from 2500 to 13,000, the insulation engineer was not handicapped. He has merely maintained an increase in thickness of the dielectric to correspond to the voltage rise. In general the situation as regards turbo insulation is satisfactory; it is true, accidental defects may occur, but periodic voltage tests tend to keep service failures at a minimum and the fact that the insulation engineer has not been handicapped seriously in space allowed, has permitted a fairly large factor of safety to be maintained.

---

[1] Research Laboratory, Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa.

*Presented at Regional Meeting of the A. I. E. E., District No. 2, Baltimore, Md., April 17-19, 1928.*

We are now at the beginning of a further advance in standard voltages as well as kv-a. rating and size of generating units, and the first increase for many years has been proposed from 13,800 to 22,000 volts. On the basis of previous experience and practise a proportional increase in insulation thickness will take care of this change. This being permitted no particular difficulty arises so far as the insulation itself is concerned except to cut down the rate of removal of heat. But it is highly desirable that the insulation carry more of its share of the load in the way of assuming higher working stresses. This thought is not new as the necessity and importance of higher voltage stresses on the insulation in high-voltage applications is already felt but it does call attention to the need of information on what may be expected in the near future in this respect.

The problem has therefore been attacked from the standpoint of a more severe service on the insulation. The starting point of the study has been the weaknesses of the present insulation with a view of determining necessary improvements within the insulation itself but the problem of what may be done outside the insulation to relieve the situation is also considered. Incidentally the effects of one or two other developments on the insulation problem are mentioned.

### MICA FOLIUM UNDER SERVICE CONDITIONS

In order to interpret actual results it will be well to get a clear picture of the insulation studied and the same under service conditions. Mica folium, as it is called, is made of large sheets of paper upon which mica is fastened by means of a bond. The insulation, considered first, is shellac as the bond, holding overlapping mica flakes of two to four sq. in. area. A layer of bond is also placed over the mica surface, and after baking to dryness, the sheet is wrapped around the bar to the desired number of turns and ironed down with heat and pressure until practically a solid insulation is obtained of mica bond and paper. The resultant bars or coils are then wound in the stator slot, a paper slot liner being used to prevent injury to the insulation surface during winding.

Using the shellac bond this insulation has been in use for many years and has given dependable service. Mica of course is a good insulator if it can be held in place and the purpose of the bond and paper is in general to hold the mica although they do have a considerable insulating value. The chief point to be considered with respect to bond and paper is that they be so chosen that they do not detract too much from the insulating value of the mica.

Service conditions in the machine impose heat, voltage, and mechanical vibration effects. Insulation temperatures having been reduced to approximately 100 deg. cent., satisfactory service is obtained so far as temperature is concerned and in general operating voltage stresses in volts per mil have been kept to values allowing a considerable factor of safety. However, in machines with voltages of the order of 5000 or 6000 from conductor to ground, one voltage effect has developed, that of corona, sufficient in strength to remove all organic material with which it comes in contact. The paper slot lining and paper wrapper of the coil may disappear entirely or at least be found to be eaten away in small spots under the corona arcs. After several years service, however, coils have been examined and no effect found on even the first layer of mica; furthermore, beyond the loss of the paper wrapper, no effect on the dielectric strength has been observed.

One of the defects of mica folium has been the slight tendency to swell. The defect has its good point in that it keeps the coil tight in the slot but it was not known just why it swelled or what other features might be introduced. During the present study, most of the cause of this swelling has been definitely proved to be due to a freeing of a slight amount of solvent vapors which, linked with the fact that the insulation is non-porous and tends to retain the vapors, permits the formation of slight internal pressures. By making a porous insulation the vapors could be allowed to escape but it was felt that this would tend to lower the dielectrical strength somewhat which is undesirable. Further studies as to the effect of the swelling confirmed the prediction that the vapor pockets allowed internal corona[2] creating an internal power loss of small amount which add two or three deg. cent. to the insulation temperature. This is not serious at operating voltages but tend to increase faster than the voltage so that at higher voltage gradients it would not be desirable. With this information at hand, coils from machines in service have been examined to see if any internal deterioration of the bond could be detected but none was found. The absence of oxygen accounts for this, the concentration of heat in the arcs being evidently too small to do damage by themselves. One possibility of preventing swelling suggests itself in the way of completely removing all the absorbed solvent before winding the coil; dry shellac has excellent properties but it has not been determined if such is feasible as yet. The work has been directed towards obtaining a bond which lends itself readily to obtaining the desired properties more easily.

### Power Losses

In all high-voltage apparatus, an important property of the insulation is that of power losses. By this we have reference to the losses produced by the oscillation of charges within the dielectric itself and manifesting themselves as heat. These have little effect upon the total efficiency of the machine, but although the actual watts lost is not so great, they are concentrated in the dielectric, raising its temperature somewhat. Continued curing by heating tends to lower these losses by removal of more or less volatile material. Solvents would, therefore, be expected to play an important part in the production of these losses and two possibilities suggest themselves in solving the problem. Either to reduce the solvent to a minimum or to use a solvent which has better dielectric properties in itself, or both. The ideal bond would be one which could be melted and applied at temperatures well above operating temperatures, using no solvent whatever. So far the ideal bond has not been found but results show that a large reduction in losses is possible by a choice of bond, having low losses in itself and soluble in a solvent of low loss, with a reduction of this solvent to a negligible quantity in the finished insulation.

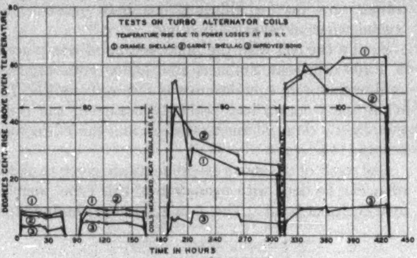

Fig. 1

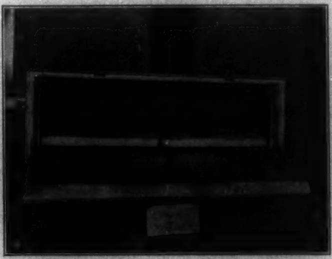

Fig. 2

The curves of Fig. 1 show comparative data on standard mica folium with shellac bond and with a bond recently developed along the lines mentioned above. Since the actual watts loss is of little importance, the temperature rise being of more importance, the temperature rise is used as ordinates in the data. The abscissa is the time in hours that the voltage of 20 kv. is applied to an insulation design for 13,000-volt operation. Attention is called especially to the importance of power losses in case higher voltage stresses are imposed. As a general rule in a 13,000-volt machine, approximately 8000 volts exists across the insulation. More than twice that stress is applied in this case, and it is evident that the losses in the standard folium are too high; on the other hand, the improved bond withstands the voltage readily. Possibly considerably higher temperatures could be used on the latter without sacrificing all the gain over standard folium. The curves also give an idea of the rise in losses with temperature of the insulation.

Fig. 2 is an illustration of the apparatus used in the study of the coils, temperatures being taken by thermocouples inserted in the hollow conductors of the bars. Machine temperatures were imitated by means of a thermostatically controlled oven and the slots by means of metal clamps. Gaps between clamps give the effect of vent ducts, gaps of one-half in., one in., and seven in. being used.

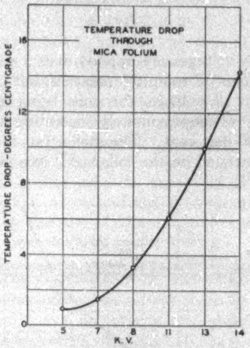

Fig. 3

The curve of Fig. 3 is a characteristic one representing the variation in losses with voltage stress and brings out the fact that the losses increase faster than the voltage. Assuming the equation

$$\text{loss} = E^n$$

$n$ is found to be almost exactly equal to two at 5000 or 6000 volts but increasing gradually to approximately three near the upper end of the curve.

As mentioned above, the swelling of coils due to the solvent is a factor to be considered. Comparative tests on the two bonds in the present case are found in Fig. 4 for a one-half in. gap at 80 and 100 deg. cent. machine temperature. Curve 1 is for a standard shellac folium while No. 2 is that with the new bond. The processing was done in the shop to make the test comparable. It is evident that considerable progress has been made although even a more complete removal of the solvent may be possible. If the surface layers could be preserved as will be discussed later, and the coil originally wound tightly in the slot, the tendency to remain tight rather than loosen is an advantage. A third variation in the power loss studies involves an effect observed when high voltages are applied over a period of time at an ambient of room temperature, but between each application of voltage, the coils being given a heat treatment of approximately operating temperatures around 100 deg. cent. The shellac bond is apparently dry when wound on the coils but it was predicted that some solvent is locked up or absorbed and is driven out gradually. The present test is believed to verify this prediction. The voltage used in the present case was 30,000 volts on a 13,000-volt insulation and was applied until temperature equilibrium was obtained in each case.

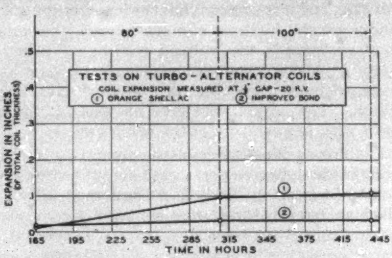

FIG. 4

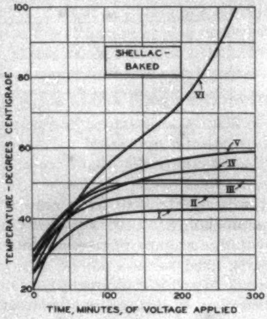

FIG. 5

Figs. 5 and 6 represent standard shellac folium and that of the new bond respectively. It will be noted in Fig. 6 that baking the coils with the improved bond, no change in loss was obtained, the variation being due to variations in room temperature but in Fig. 5 after each baking, the standard insulation showed increased losses. This was not due to voids as the coils were tightly clamped. Previous to the final curve of Fig. 5, curve *VI*, this coil was baked about 18 hr. at 115 deg. cent., the temperature-time-voltage curve going up to more than 100 deg. cent. before the test was stopped, and it was evident with the increase of losses with temperature that equilibrium has been passed and breakdown would eventually occur.

Finally the coil with the improved bond was placed in a 100 deg. cent. ambient and 30,000 volts applied until temperature equilibrium was obtained (see Fig. 7). While some curing had probably occurred, the coils were tightly clamped during the test and this effect was believed to be small.

The result of the above experiments are given to show what can be done with insulation of this type, merely by a choice of bond. The data given was obtained for coils with mixtures of the bond which were as far towards the low loss side as it was convenient to use on account of the high temperatures necessary in manufacture if bonds of lower loss are used. However, such information is important in that it indicates not only possibilities in improving insulation for the present designs of machines, but also for designs when it may be desirable to increase the stress somewhat on the insulation. So far power losses have not been considered in turbine design but we are facing the problem of increased stresses and losses in many high-voltage applications and it is not probable that we shall escape here.

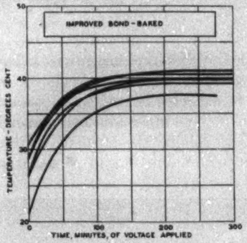

FIG. 6

One very important feature of the new bond is the flexibility of the folium as compared to shellac, and it is found possible to use several extra layers of mica which is desirable as long as the coil is good mechanically.

### BREAKDOWN TESTS

While it is not intended in this paper to suggest that higher voltage stresses be used until it becomes necessary, it is believed that enough evidence is given to indicate that the use of increased stresses may be possible and if higher and higher generated voltages become desirable as machines increase in size and output, such may become necessary. As a matter of fact there has been some increase in stresses used during the last several years. A second electrical property of insulation, that of dielectric strength, is of the utmost importance in this connection and it is doubtful if many operating engineers have an idea of the factor of safety maintained in the way of puncture voltages. Just what the factor of safety should be is a different problem but all will agree that with the large valuation involved in a single large generating unit, the factor of safety should be greater than in any other application. The problem of surges alone makes it desirable to know what the actual dielectric strength is and from this point of view, would become still more important for increased stresses. With this in mind, four coils have been tested as follows:—three coils of four ft. length designed for 22,000 volt operation using the improved insulation, were tested by using a six in. layer of tinfoil around the middle of the coil, the whole being immersed in oil. Under a continuous rise voltage test, none of the coils was punctured, all flashing over the surface at values between 150,000 and 170,000 volts. An attempt on a coil of 20 ft. in length in the straight part and three ft. extension on each end, was made in air. This also flashed over on three or four trials at about 165,000 volts. No tests were made on standard shellac folium but no great difference is to be expected on momentary tests although the improved bond will withstand the same voltage longer. It would be of interest to know what the actual puncture values are but the tests obtained were high enough to indicate a sufficiently high factor of safety even for considerably higher operating stresses than are now used. Operating stresses at present are of the order of 30 to 60 volts per mil while the puncture tests indicate values of the order of 500 volts per mil.

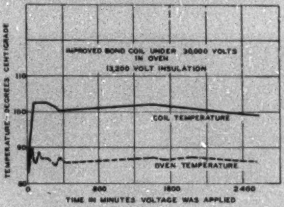

Fig. 7

## Testing Voltages

A problem which may become more or less acute upon the adoption of higher operating voltage is that of overvoltage tests. It is difficult to get quantitative data upon which to base conclusions but attention is called to the fact that the effects of voltage vary as $E^n$ where $n$ is of the order two or above and in most cases for test voltages the value of $n$ will be more nearly three. A feature of high testing voltage which has not been experienced up to the present time is that of the disruptive effects of creepage discharges on the surface of coils. Coils may be damaged to the extent of actual puncture of some of the outer layers particularly at a distance of two or three in. beyond the end of the electrode or in the machine beyond the end of the slot. Further studies will be required to determine what voltages should be chosen for tests of this type but an attempted life test on a 13,000-volt insulation using the improved bond and 40,000 volts applied between a metal clamp on the outside of a coil and the conductor, produced an effect which indicates the danger of injuring coils by the application of extremely high voltages. About three in. from the end of the electrode and extending as much as three or four in. farther, the disruptive effect of creepage charges gradually destroyed the paper and bond, loosening and dehydrating the mica so that it exhibited a bushy appearance. Breakdown finally occurred after 1140 hr. in this region while the insulation under the clamps was still in perfect condition. Further tests at 50,000 volts on the same design of coils produced the same effect and caused breakdown in a few hours. It was evident that the rate of deterioration increased rapidly between 40,000 and 50,000 volts. A test of 66,000 volts even for one minute might defeat its own purpose by damaging the surface layers of the coil unless some means of reducing these creepage effects can be devised. As shown in the following paragraphs, the corona and surface creepage effects can be reduced or removed at operating voltages and can be reduced at least, for high testing voltages.

## Corona Elimination in Turbo Stators

The phenomenon called corona made its appearance in machines as soon as voltages were developed of the order of 5000 or 6000 volts from conductor to ground. The evidence of its presence is furnished by the odor associated with ozone, which is a product of the action of corona on the oxygen of the air and it is visible to the eye under favorable conditions. While the coil is mechanically tight in the slot, there still exist some very small air-gaps due to manufacturing tolerances and irregularities of the surfaces in contact and these minute gaps are over stressed, producing corona.

So far all evidence points to the fact that the actual danger from corona is slight but there are some reasons why it should be removed if possible, as for example the coil could be held rigidly in the slot without permitting expansion as occurs when the slot liner and wrapper are eaten away. This will also eliminate the uncertainty in the minds of some designers and operators and finally may help to reduce effects of testing voltage. As much as 15 years ago engineers began to feel uneasy about its effects on insulation and the problem of its elimination was considered. It was evident that all that was necessary was to remove the voltage stress in the air-gap, which could be done by bringing ground potential to the surface of the solid insulation, by making the surface a conductor. Accordingly metallic paints and tinfoil were tried and actually put into some machines. The tinfoil was applied with an outer covering of cotton tape and was grounded at but one point, otherwise the steel laminations would be short circuited. The paints were usually too high in resistance to be efficient. Along with the difficulties of applying and the fact that corona in mica insulated machines without this kind of protection did little damage the problem was dropped as mica was generally used. However, it has seemed more and more desirable to remove the corona if such could be done without too much difficulty and with the possibility of higher generated voltages the problem will become even more important. For this reason the present study has been extended to include the problem.

Some features of a solution of the corona problem are self evident. The conducting film to be placed on the coil must be continuous and adhere to the insulation surface. Further, the resistance of the film must be large enough to prevent eddy currents and in case of grounding at more than one point, should also be high enough to prevent circulating currents. Metallic films in general fall in a class with resistances too low to be used and at best could be grounded at but one point. In case this ground was broken most of the effectiveness of the film might be lost. For this reason a film of high enough resistance to permit of more or less continuous grounding throughout the slot is the ideal. The upper value of resistance is determined by a maximum value which will permit a charging of the condenser between the conductor and film to the full potential of the machine during a half cycle. Calculations show that the resistance per unit length of coil can be as much as a megohm even for relatively few grounding points. On the other hand, a minimum of 1000 or 2000 ohm per in. length of coil is sufficient to eliminate eddy and circulating currents so that a wide range of workable resistance exists.

One special graphitic paint has been found to adopt itself rather readily to the purpose. By controlling the concentration the resistance can be made the order desired and high enough so that continuous grounding can be used if necessary. It is not improbable that a number of materials can be found which have the proper characteristics but the one mentioned seems to have most of the desirable properties in case a smooth surface is furnished for its application. A problem, concerning which there is some uncertainty as yet, is that of the life of the film at the vent ducts under the action of the high velocity air currents used in cooling the machine. To avoid the possible destruction of the film at this point, the film can be protected by retaining the fish paper slot liner, perforating this paper layer at points between each vent duct along the side of the coil and painting over the hole on both sides with the same graphitic paint so that the film also covers the edge of the paper in the perforation. This has been shown to give perfect grounding and since the paper lining of the slot is protected from the corona it should protect the film over a long period of the life of the insulation.

The conducting film (See Fig. 10) just discussed removes the corona throughout the slot but at the end of the slot corona occurs which gradually tends to eat away the film itself. Furthermore, this corona will of course tend to destroy the organic material on the surface of the coil and must be eliminated before the device is complete. Burying the end of the film deep in a solid insulation suggests itself as a means of eliminating this defect, but the space available is small between the coils and needed for ventilation purposes. Two other methods have also been suggested and one will be given which has been perfected to the point where it is believed to be practical.

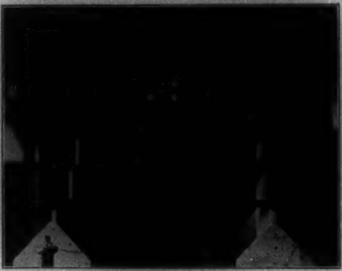

FIG. 8

If an extension of the conducting layer is made a few inches beyond the slot, a capacity current flows along this extension charging up the condenser between the layer and the conductor. The capacity, of course, is small, being of the order of 15 $\mu \mu$ f. per in. length of coil, and the currents flowing are also small, decreasing towards the end of the extension. Calculation shows however, that if resistances of the order of 100 megohms per in. length of coil could be found the $I R$ drop along this extension could be made to take care of most of the voltage difference between the conductor and ground so that at the end of the extension, the voltage is too low to ionize the air, thus removing the corona completely. Dependable materials giving the desired resistance have been found available and some idea of the effectiveness of the device is obtained from Fig. 8. *A* represents the corona between a laminated structure and coil at 30,000 volts applied with no attempt at elimination, *B* shows the effect of the graphitic layer under the same conditions with the end effect, which is later eliminated in *C*. It is possible to damp out 30,000 volts with a minimum of approximately a five in. extension; 8000 volts can be taken care of with approximately a two in. extension, leaving the drop at the end below the corona point.

The accurate solution of the problem involved in the extension is a particular solution of the transmission line equation for parallel conductors with uniformly distributed resistance and capacity, the differential equation being

$$\frac{\partial^2 E}{\partial x^2} = C R \frac{\partial E}{\partial t}$$

The inductance is considered negligible.

The solution of this equation may be found in engineering texts but for practical purposes the order of magnitude of the resistance can be obtained from the approximate equation

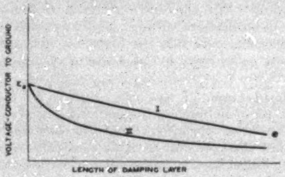

Fig. 9

$$r = \frac{2\,(E_0 - e)}{C\,\pi\,f\,l^2\,10^{-12}\,E_0}$$

Here *r* is the resistance per unit length, $E_0$ the applied voltage, *e* the residual voltage at the end of the extension, *C* the capacity per unit length, *l* the length of the extension, and *f* the frequency. For lengths, permissible in practise, the value of *r* is found to be of the order of 100 megohms per in. length of coil. The values actually used are approximately 500 megohms per in. as measured by a 1000 volt megger. The resistance of materials of the type available vary with voltage of course, and are somewhat lower under machine voltages.

A feature of the damping resistance or extension which may be of interest is represented in Fig. 9. In order to get a uniform drop in voltage per inch of extension, curve *I*, which is the ideal way, the resistance per unit length would be required to vary inversely as curve *II* of the Figure. This is impossible in practise where the resistance is constant per unit length so that the voltage drops off more nearly as curve *II*.

In building the extension it has been found necessary to use a porous material to hold the resistance material and a special asbestos tape with the organic filler burned out. It has been possible to do this without loosing much of the mechanical strength of the tape and some of this loss is regained when fastened to the coil surface with a bond. The tape is then filled with the high resistance material and electrical connection made with the graphitic layer, Fig. 10 shows the complete assembly.

## Corona in End Windings

A problem which has caused some discussion in the past has to do with the formation of corona on the metal parts of the structure bracing the end windings. So far this problem has not been of much importance for the type of bracing used with mica folium coils, as enough insulation could be used between the metal parts and the coils, that operating voltages could produce only a soft, harmless corona at most. The question may be revived, however, with voltage increases in machines, but the problem in any case can not be considered serious since types of bracing can be used in which extra insulation can be added to bring the stresses in the air-gap below the corona point. It is a simple matter to calculate the air-gap stresses on the basis of the insulation thickness and dielectric constants or in other words, to calculate the insulation thickness necessary. The metal parts in such cases are to be assumed to be at ground potential, that is, at the average of the coil potentials, thus insuring that no high voltages are built up across the insulation at any point. From this point of view it is necessary to ground all metal parts, but in general this is more important in that it permits better mechanical features.

Reference was made above to the effects on insulation of corona in hydrogen. The usual deterioration of organic material in the presence of air under corona is due chiefly to oxidation. With hydrogen this effect will be absent[3] and the bad effects usually associated with corona should disappear as long as the arc temperatures are not too high where they actually strike the insulation. Even intense corona has been found to have but slow effect under short tests of a few weeks.

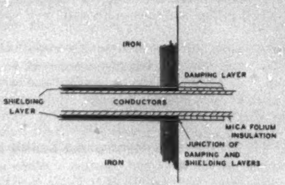

Fig. 10

For the same reason, the absence of oxygen protects laminated insulation from internal corona.

## Summary

A summary of the above discussion may be made as follows:

1. That as generated voltages are increased it may become necessary to use higher voltage stresses in volts per mil thickness of the insulation, which in turn

---

[3] Knowlton, Rice, and Freiburghouse, *Hydrogen as a Cooling Medium for Electrical Machinery*, Trans. A. I. E. E., Vol. XLIV, 1925, p. 922.

may necessitate the use of a lower power factor material in order that excessive heating be avoided.

2. That a very decided improvement in this property can be obtained for mica folium by a choice of bond containing only a negligible amount of a low loss solvent or other volatile material.

3. That the reduction of the solvent decreases the tendency of such coils to expand, and it has been found that the swelling is reduced to a small fraction of that of older insulations.

4. That the factor of safety to puncture as determined by continuous rise voltage tests is considerably more than is ordinarily considered necessary for most applications and that the results indicate higher stresses on mica folium could be used.

5. That so far the effects of corona have not been serious and in no case has the mica been affected, yet to protect the organic surface of the coil, it may be desirable to eliminate corona at present voltages as well as at higher voltages. In hydrogen it will not be so important.

6. That a method of eliminating corona on armature coils has been devised which is believed to be practical.

## Discussion

**P. L. Alger:** Mr. Hill has given us a very interesting and suggestive article, which I am sure will be a valuable contribution to the literature. Mr. Hill evidently believes, and I fully agree with him, that the whole subject of insulation of armature coils hinges on two points, the first being the choice of the sticker to hold the mica together, and the second being how to avoid corona discharges.

Any sticker used must be not only a good insulator, heat resistant, and acid resistant, but it must also be so flexible that it can be applied, and the coil can be handled and taken out of the machine and put back without damage, while at the same time it must have so high a boiling point or melting point that it will not flow under operating temperatures. In cables, flowing is permitted because the insulating material is held by a sheath, but in an armature coil this is not possible. Since any material like varnish is inherently flexible, if it has a low boiling point, and brittle if it has a high boiling point, these two requirements of flexibility and high temperature resistance are incompatible, and it is very difficult to strike a balance between the two. As Mr. Hill has said, shellac is all right at low temperatures, but when heated it loses alcohol and becomes very brittle. We have found that black asphalt varnishes give the best results, partly because they contain many ingredients of slightly different boiling points, so that by aging them to any desired degree, the boiling point can be raised just enough to avoid swelling in operation, while at the same time the maximum of flexibility is secured.

In regard to the corona question, it is interesting to think at how low a voltage corona occurs in armature coils. The dielectric constant of mica insulation is about 3 in magnitude, which means that the air in series with the insulation is subjected to a stress about three times as great as that in the insulation itself. This, coupled with the fact that the external air spaces are irregular, gives actual maximum stresses at certain points in the air surrounding the coil, of five or six times that in the insulation and therefore, external corona begins at very low voltages—as a matter of fact, at about 3000 or 4000 volts on a 22,000-volt coil. It is, therefore, very difficult to avoid it completely. We have found that, by using simple asbestos tape armor on the outside of the coil, good results are obtained. Asbestos is sufficiently conducting to hold down the potential of the coil surface near the embedded parts below the sparking voltages.

Great variations in surface conductivity occur with changes in humidity, with dust, and with the type of varnish coating employed on the end windings, but in general values of surface resistivity of the order of 50 megohms per in. of perimeter per in. length of coil give good results. The accumulation of dust on the end windings of machines in service acts initially as corona protection, thus accounting for the diminution of ozone often noticed after machines have operated for some time. Too much dirt, however, lowers the surface resistivity too greatly, causing increased discharges.

Fortunately, corona can be permitted without giving much operating trouble, as shown by the fact that two 22,000-volt synchronous condensers have been operating in India for the past five years without any corona protection whatever, but with insulation consisting of mica tape and black asphalt varnishes around the entire coil. These machines have so much corona on the end windings that the lines between the terminal coils of each phase and the adjacent end windings of the next phase are continually illuminated by a line of light during operation. In spite of this, they have operated for five years without noticeable deterioration. Thus, while external corona is of great importance, especially in high-potential tests, it is not really a thing to be regarded as a source of danger to mica-insulated machines in normal operating conditions.

**S. L. Henderson:** I was very glad to have confirmation from Mr. Alger of so much of the material that was in Mr. Hill's paper. It has been very interesting to me, as a machine designer, to realize that the problems of cable manufacture are much the same as we have in our insulations. We are bothered with moisture and voids in the insulations and have the problem of porosity in the paper. We can pick a paper that is low in moisture but too brittle to use, and we are working between the same limits. We are also trying to reach the same solution of finding an insulation that will remain through its life practically as good as the day it was made.

**C. F. Hill:** I was much interested in Mr. Alger's remarks and note in particular that his experiences in general are similar to our own. One point in particular, involving the use of asbestos tape armor, is of especial interest. We have found that asbestos tape at room temperature takes up moisture until it is sufficiently conducting to make a fairly good shield over a coil surface and have found that it is especially valuable on coils at room temperatures when high-voltage testing is done as it tends to prevent static discharges over the surface which might mar the surface layers of the coil. Asbestos, however, is a rather good insulator when dry as in a hot machine and our experience has been that it then does not eliminate corona. We have also found it desirable to bake out the organic filler of asbestos tape before applying to the coil in order to insure that static discharges under high-voltage testing may not burn conducting paths through the tape. This is especially necessary, for example, in the case of 22,000-volt insulation when applying up to 70,000 and 80,000 volts.

Mr. Alger's remarks on corona in operating machines are in general agreement with our experiences. In the slot, however, corona will attack all exposed organic material and it is to preserve the surface that corona eliminators are applied and then only for higher voltage operation. As to the choice of bond used, any bond must be a compromise of properties and for extremely high-voltage operation the electrical properties must assume an important role. An attempt was made in the paper to give a complete picture of the requirements for turbo coil insulation and to give an idea of what could be done in the way of approaching, at least, a good insulation. Shellac from alcohol solution is at a disadvantage in some respects. On the other hand, shellac with the alcohol omitted entirely can be made with excellent properties, far better mechanically than asphaltic bonds, but difficult to process at present into this type of insulation. We believe that the low-loss characteristic of asphaltic bond gives it some advantage as yet for high-voltage operation.

# The Gould Street Generating Station of the Consolidated Gas, Electric Light and Power Company

BY A. S. LOIZEAUX[1]
Associate, A. I. E. E.

***Synopsis.***—*The paper is descriptive of the Gould St. Plant. Pulverized coal is prepared in a separate building. Only one boiler is provided per turbine, each boiler delivering a maximum of 520,000 pounds of steam per hour. Automatic control is provided for the electric drive of boiler auxiliaries, electric auxiliaries being used throughout the plant. 250 volt exciter and 460 volt house turbine are on main generator shaft. Switch house is of isolated phase construction with vertical operation of switches. Actual costs are given for the first unit, with estimated costs for completed plant, resulting in costs for the completed plant of $88 per kw. for normal output and $80 per kw. for maximum output.*

* * * * *

THE new Gould Street Plant which began operation in January, 1927, is located in the City of Baltimore on the Patapsco River, an arm of the Chesapeake Bay. This waterfront site was formerly the power plant location of the Baltimore Electric Company which had been purchased by the Consolidated Company in 1908, and has not been in operation since 1918. The comparison between the old plant and the new illustrates the great advance in the art of electric power generation during a period of 20 years, the new units having twelve times the capacity of the old, with a coal rate of the new plant less than one-half that of the old plant.

From the standpoint of nearness to important load centers the site is highly desirable so that the energy is distributed by underground cable at 13,200 volts without transformation. The plot measures 405 ft. by 635 ft. and is of sufficient size to supply load growth for perhaps 10 years, when the progress of the art of power generation will probably make it desirable to begin anew in another location with higher pressures, higher temperatures, and, perhaps, a materially different heat cycle.

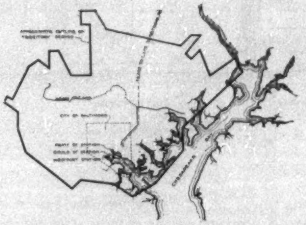

FIG. 1--TERRITORY SERVED BY THE CONSOLIDATED GAS, ELECTRIC LIGHT & POWER CO. SYSTEM

### SOURCES OF POWER IN BALTIMORE

The accompanying map, Fig. 1, shows the territory served by the Baltimore plants and indicates the city limits and the location of the Westport and Gould St. plants; also the former railways plant at Pratt St.

The Westport plant began operation in 1905 and provided for growth of load through 1926, a period of 21 years. Westport has a 25-cycle capacity of 125,000 kw. and 60-cycle capacity of 40,000 kw.

The Pratt St. plant was formerly a railway generating station but now contains only one standby unit of 20,000-kw. capacity.

### HYDRO ENERGY

A considerable part of the electric energy used in Baltimore comes from the Holtwood plant of the Pennsylvania Water and Power Co. The Holtwood plant is located on the Susquehanna River at Holtwood, Pennsylvania, and consists of a hydroelectric plant with 87,000 kw. in 25-cycle capacity and 24,000 kw. in 60-cycle capacity. There is also a steam station at Holtwood of 25,000-kw., 60-cycle capacity. The transmission lines from Holtwood to Baltimore are 25-cycle, 66,000-volt, 40 mi. long.

### GOULD STREET GENERATING CAPACITY

Gould St. has one 36,000-kw. unit operating and a second duplicate unit which will begin operation in April, 1928. The plant is designed for four 36,000-kw. units, a total of 144,000 kw. at 60 cycles.

### ARRANGEMENT OF PLANT

The general view in Fig. 2 shows the arrangement of the plant, the power house being built on the water's edge. The coal unloading tower is placed about the center of the bulkhead line. Coal is transported by belts to the pulverizing plant. The buildings of the former generating plant were used, the old boiler house being transformed into a pulverizing plant and the old turbine room into a service building and machine shop. The switch house is a new building on the north end of the property toward the city, the power station and switch house being connected by underground concrete tunnels.

*Presented at the Regional Meeting of the A. I. E. E., District No. 2, Baltimore, Md., April 17-19, 1928.*

## FOUNDATIONS

The waterfront end of the site was reclaimed from the river by filling in. The land adjacent to the power plant is to be a city pier, providing a ship channel 35 ft. in depth. These conditions made it necessary to use reinforced concrete caissons to support the end of the plant abutting on the water. Fig. 3 shows a plan of foundations. The caissons are eight in number, some circular and some oval, and are sunk to a depth of 40 ft. to a bottom of gravel and stiff clay. This construction insures that the 35-ft. deep channel will never threaten the stability of the power house.

Fig. 2—Aerial View of Generating Station

The coal unloading tower rests on two oblong caissons sunk to a depth of 70 ft. The forms for these caissons were built of timber and steel and launched like boats and sunk into place, the open method of sinking used to 50 ft., and the compressed air method, from 50 ft. to completion. A third caisson is provided to support an additional or twin coaling tower that will be required for the completed plant.

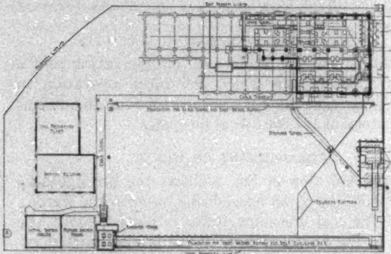

Fig. 3—Foundation Plan for Buildings, Coal Handling Equipment, and Coal Storage

The waterfront end of the coal field rests on a relieving platform in order to prevent the weight of coal from moving the soft underlying material. This relieving platform rests on wooden piles driven on 3-ft. 8-in. centers and consists of a reinforced concrete slab 18-in. thick and good for a load of 2630 lb. per sq. ft., making it safe to store coal 40 ft. deep over the area.

Other foundations for buildings, runways for coaling bridge, and foundations for turbines are all supported by wooden piling, capped with reinforced concrete mats. The mat for the turbine foundation is 3 ft. thick and is isolated from other building foundations.

## COAL SUPPLY

The coal used in Baltimore power houses comes from upper West Virginia and central Pennsylvania coal fields, over three railroad systems. A differential of 25 cents per gross ton exists in favor of water delivery of coal as compared with rail delivery. The result of this differential is that in all of the three plants coal is received by water delivery.

The company maintains its own fleet of two steam tugs and nine coal scows to transport coal from the unloading piers of the railroads to the waterfront unloading equipment at the several stations.

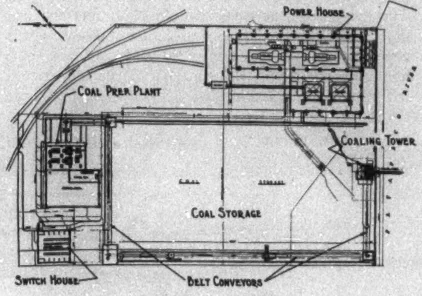

Fig. 4—General Plan of Station showing Power House, Switch House, Coal Preparation Plant, Coal Handling Equipment, and Storage Lot

During the year 1927, the Baltimore plants consumed 301,666 short tons of coal, the average analysis being 14,090 B. t. u. and an ash content average of 8.27 per cent.

## COAL HANDLING

At the Westport Plant, there are two unloading towers, both electrically operated, and an aerial cable for stocking out and reclaiming coal, the maximum stock of coal on the lot at one time being 76,025 tons.

At Gould St. the coal field is designed for a traveling bridge and the lot will hold 70,000 tons when stored to a depth of 40 ft. Fig. 4 is a general plan of the station and shows the coal handling equipment and coal storage lot.

Coal is unloaded by an electrically-operated tower with Mead Morrison equipment and a two-ton bucket, the present tower having an all-day capacity of 165 tons per hour. The future Twin tower will increase the capacity to 300 tons per hour. The coal, after being unloaded in the tower hopper, is received by a Bradford breaker 12 ft. by 19 ft. This breaker reduces the coal to a maximum size of 1¼ in. and removes trash, delivering such material through a chute to an outside location.

### BELT CONVEYERS

The belt conveyer system consists of five belts with two trippers. The first conveyer receives coal from the hopper under the breaker in the coaling tower and travels parallel to the bulkhead to the southwest corner of the lot, where it delivers coal to conveyer No. 2. This belt carries the coal along the western side of the field and either stocks the coal out in the field by means of a tripper, or delivers it to a secondary crusher.

The secondary crusher is installed in a concrete pit at the junction of No. 2 and No. 3 belts and receives coal by gravity from conveyer No. 2. This crusher is a hammer mill of steel plate construction built by the Pennsylvania Crusher Co. It is rated at 200 tons per hour but can handle 400 tons of dry friable coal.

No. 3 conveyer carries the coal along the northern edge of the field. It is inclined at an angle of 19 deg., and lifts the coal 77 ft. from the pit under the hammer mill to the No. 4 conveyer, which carries the coal into the end of the preparation plant above the bunkers. No. 4 conveyer is also inclined 19 deg. and lifts the coal 24 ft.

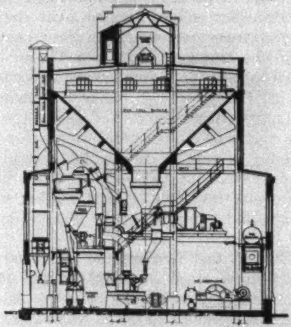

FIG. 5—CROSS-SECTION OF COAL PREPARATION PLANT

No. 5 conveyer distributes the coal in the raw coal bunkers by means of a traveling tripper.

All of the conveyers are equipped with 36 in. rubber belts and have a capacity of 336 tons per hour. There is no speed adjustment on any of the belts; the ribbon principle is used, the rate of feed or thickness of ribbon of coal is regulated by the apron feeder which delivers coal to the Bradford breaker. The flow is continuous from this point until the coal is delivered to the preparation plant bunkers. A similar regulation is provided at the traveling hopper above No. 2 conveyer when coal is reclaimed from storage. Electrical interlocks are provided so that in the event of trouble on any belt all preceding equipment including apron feeder and breaker will be immediately stopped preventing an accumulation of coal at the junction points.

The belts are arranged so that any one of three operations may take place; *viz.*, tower to preparation plant bunkers, tower to storage, or storage to bunkers. The motors for these conveyer belts, five in number, are controlled by push buttons which operate single-step primary resistance starters, the resistance being cut out by the operation of a small motor driven definite time relay.

### STORAGE AND RECLAIMING EQUIPMENT

At the present time coal is being stocked out and reclaimed by a gasoline engine driven, crawler crane, equipped with a one-yard grab bucket. The capacity of this rig is about 60 tons per hour.

When the third generating unit is installed, it will be necessary to purchase the traveling bridge. The runways for the bridge are in place, since the concrete work was so intimately connected with the supports for No. 2 conveyer on the west side and the cable tunnels on the east side, it was economical to pour them while the concrete plant was set up.

### COAL WEIGHING AND SAMPLING

Two Merrick weightometers are used to weigh the coal in transit. One is installed on No. 1 conveyer and weighs all coal received at the plant. A second is located on No. 4 conveyer and gives a record of the coal sent to the preparation plant bunkers.

A Dings magnetic pulley is used at the head of No. 4 conveyer. It serves to prevent any magnetic material from getting into the bunkers above the pulverizing mills. This gives triple protection since the Bradford breaker removes the larger pieces of foreign material from the coal, the hammer mill is equipped with tramp iron pockets which catch a part of the foreign material and the magnetic pulley throws out the nails, small bolts, etc., that remain.

An automatic coal sampling device is now being installed at the junction of conveyers No. 1 and No. 2. It consists of a rocker shaft carrying several 4-in. tubes for collecting the gross sample, and a Sturtevant motor driven sample crusher and splitter. It is arranged to run whenever No. 1 conveyer is in operation, and does not require a separate control. The gross sample taken by the tubes will average one pound per ton and will be taken simultaneously at several points in the ribbon of coal as it leaves the head pulley of the conveyer. This gross sample will be crushed and split so that a sample of about two pounds per hundred tons will be collected for the laboratory while the discard will run by gravity onto No. 2 belt and pass on with the other coal.

### COAL PREPARATION PLANT

The general arrangement of the coal preparation plant is shown in Fig. 5. The building was originally the boiler house of the former plant. All but two of the original boilers were removed, the two remaining boilers being used to supply steam during the construction period. The building required considerable alteration including the removal of the old coal bunkers and the installation of new bunkers with increased slope so that the coal would flow to the discharge gates at the bottom of the bunkers, the capacity of the bunkers being approximately 900 tons. The coal gates at the bottom of the bunkers control the flow of coal to Richardson automatic scales now being installed. There are two scales for each mill. From the discharge hopper of the Richardson scales the coal flows to two feeders for each mill. The original installation included steam driers but these have been replaced by the system of drying in the mill. Air from a tubular air heater using steam at boiler pressure is blown into the circulating air as it enters the mill providing hot dry air to absorb moisture from the coal in the mill. Sufficient air is bled off from the top of the cyclone to discharge the moisture picked up and keep the humidity of the air in the circulating system below the dew point. This air bled off is replaced by heated air coming from the air heater which is mixed with the re-circulating air before it enters the mill. The cyclones in which the air and coal are separated discharge the coal into the hoppers above the coal transport pumps. The air drawn off from the circulating system passes through a concentrator, in which the heavier solids are removed, and from there it passes through a washer before being vented to the atmosphere. This washer is of the vertical type, in which the gases are washed by steam and water sprays.

The machinery for preparing and transporting the coal comprises two 20-ton Raymond roller mills, each with a separate exhauster and circulating system and steam air heater; two transport pumps, each having a nominal rate of capacity of 40 tons per hour, and two 735-cu. ft. two-stage motor driven air compressors.

The construction within the mill house is such that wherever possible, ledges, or resting places for coal dust have been avoided. As two of the old boilers were left in service for furnishing construction steam, a cinder block wall was built to separate the grinding room from that section of the old building where the boilers remain. Sash in the preparation plant opens outward and is of the plain glass type, providing a 10 per cent area of plain glass, as prescribed by the underwriters.

All of the equipment in the preparation plant is electrically driven, using 440-volt, three-phase, 60-cycle, squirrel-cage type motors. There are no circuit interrupting devices in the preparation plant. Motors are controlled from water-tight push buttons operating contactors which are located in a control room, which is located in the turbine room of the old plant. Sequence interlocks are provided on the controls to prevent stopping equipment in incorrect order and consequent flooding or jamming of the coal feeding system. Small motors are thrown directly across the line, but the motors for the mills, mill exhausters, dryer exhauster, transport pumps, and air compressors are started by primary resistance type contactor control. Resistance grids are in the control room. Lead covered wire and cable are used for the power circuits. Control buttons are mounted adjacent to each piece of apparatus and also on a control board. The operator in charge of the grinding also controls from this board the switching valves in the coal lines over the bunkers in the boiler house.

### COAL TRANSPORT LINES AND COAL BUNKERS

Coal is pulverized in the mills so that 70 per cent will pass through a 200 mesh screen. After collection in the cyclones, pulverized coal enters the transport pumps and in combination with compressed air is transported through 6 in. pipe lines about 750 ft. long to the bunkers in the power house. The transport pumps and pipe lines are in duplicate and are so arranged that either pump can handle the output of either or both mills. The two boiler bunkers may be fed by either of the transport lines, selection being obtained by electrically operated transport valves located over the bunkers and controlled from the preparation plant master panel. Paralleling the transport lines is a 1½-in. line with connections to each for purging them with compressed air. The coal level in the bunkers is indicated on individual boiler control panels and also on the preparation plant master panel. A specially developed device takes periodic "soundings" in the bunkers and operates Selsyn transmitters for this service. Two high level paddles are also installed in each bunker to give a flashing lamp indication when the bunkers are nearly full.

The powdered fuel bunkers are each 100 ton, V-shaped, structural steel, insulated on the outside to prevent condensation inside the bunker. All parts of the bunkers are welded and tested water-tight.

### CROSS-SECTION OF POWER HOUSE

Fig. 6 is a cross-section of the power house showing a rather compact arrangement of equipment, yet providing ample space for operation. Abundant natural light and ventilation is provided for both turbine room and boiler room. A pipe gallery provides for longitudinal runs of pipes. The electrical gallery is open to the turbine room and on the same level as the turbine floor giving easy access to electrical operation.

### COAL FEEDERS

The coal is fed by four quadruplex screw feeders per boiler to sixteen Lopulco type burners through 6-in. pipes crisscrossed to prevent stratification in the furnace in the event of outage of one or more feeder groups.

### FURNACE

Three sides of the furnace are water-cooled by fin-tube surface backed by special tile, rock wool insulation and steel casing. The front wall is of firebrick, cooled by the preheated secondary air, admitted to the furnace through ports at sixteen levels in this wall. A water screen interconnected with the rear wall circulating system protects the inclined floor of the furnace which forms the ash hopper.

### AIR SUPPLY AND GAS REMOVAL

Primary air, used to convey powdered fuel from the screw feeders to the burners, is a mixture of preheated air tapped from the secondary duct and tempered with room air. Primary air is supplied by two fans per boiler, connected on the discharge by an air bus, which makes any fan available for either boiler. Two forced draft fans per boiler furnish the secondary air taken from the room and discharged into a plenum chamber directly ahead of a C-type plate preheater mounted above the gas outlet of the boiler.

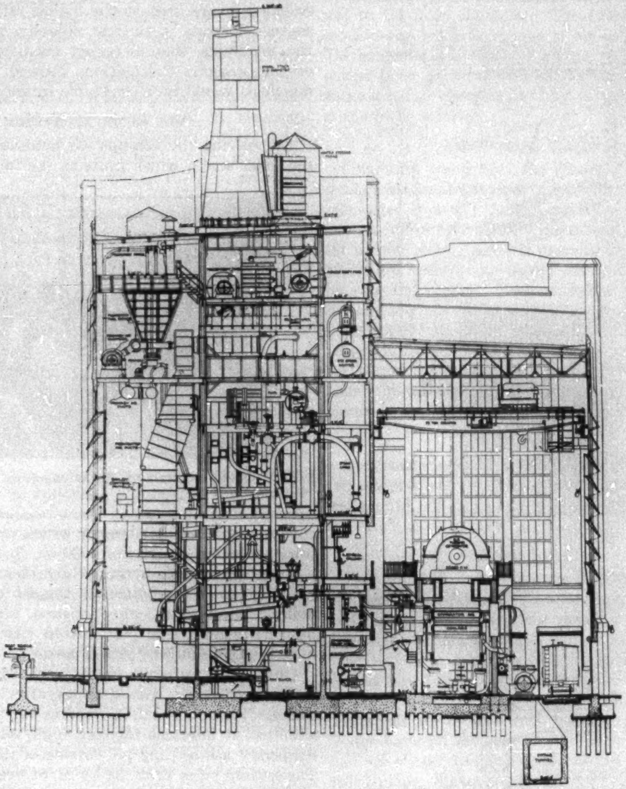

FIG. 6—CROSS-SECTION OF TURBINE ROOM AND BOILER HOUSE

Tertiary air is taken from the secondary air duct for admission around the burners.

The gases leaving the preheater are removed by two induced draft fans and discharged into an eleven-ft. diameter self-supporting unlined steel stack, one per boiler, extending 213 ft. above the burner arch.

### BOILER

The use of one boiler for a 36,000-kw. turbine with only one additional boiler as a spare unit marks an advance in plant design. Each steam generating unit has a maximum output of 520,000 lb. per hour at 450 lb. drum pressure and 725 deg. fahr. superheater outlet temperature, which is sufficient for about 46,000 kw. turbine capacity. Reserve capacity gained by increased size of boiler auxiliaries even at some sacrifice in normal operating economy, was found to be more economical than the addition of spare boiler units. Four turbines will ultimately be supplied by five boilers. Fig. 7 is a section of boiler and furnace.

Several features in the design of the boiler, a conventional B & W cross drum steel encased type, were unique. It was the first boiler at 450 lb. pressure to have 4-in. tubes. A considerable increase in heating surface was gained at small expense by extension of tube length from 22 ft. to 24 ft. Modifications in the manufacturer's previous design allowed an advance from 385 pounds to 450 pounds operating pressure. The drum diameter, 60-in., was the largest attempted for that pressure at that time, and the length of 34 ft. was the greatest that the manufacturer could furnish without a girth seam. Two steam outlets were insisted upon. General Electric steam flow meters modified for use as water level indicators and recorders are installed at the operating floor level.

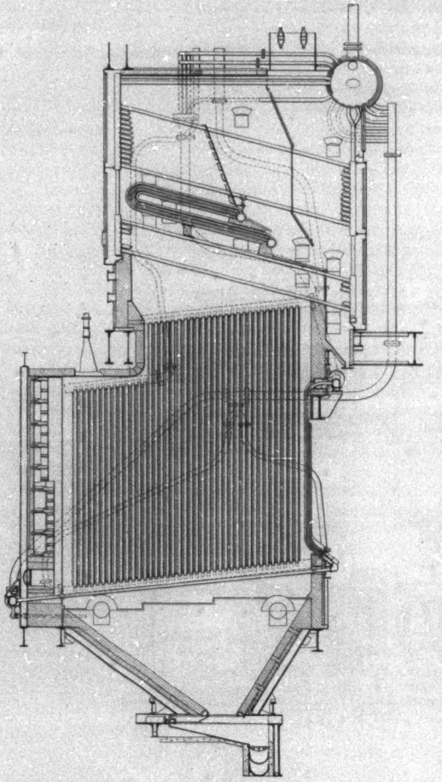

Fig. 7—Cross-Section of Boiler and Furnace

### Superheater

The superheater is of three-pass hair pin loop construction of the interdeck type and is located between the 5th and 6th rows of boiler tubes. To avoid excessive pressure drop at the higher ratings and a consequent decrease in turbine capacity, the diameter of the manifolds was increased considerably over the original design. Calculations showed that the larger manifolds would be a profitable investment.

### Ash Removal System

Ash leaving the combustion chamber falls through the water screen which protects the furnace floor, and collects in the ash pit hopper which is lined with fire brick and has a capacity of 4000 cu. ft.

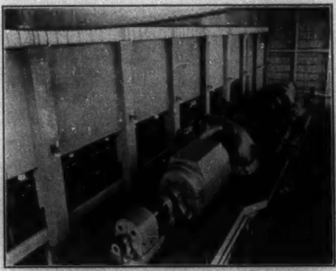

Fig. 8—View of Turbine Room showing No. 1 and No. 2 Units

Three horizontal, hydraulically operated ash gates are provided on the bottom of the ash hopper for each boiler. Those gates, when opened, allow the ash to drop on inclined feed plates from which it is washed into the main sluice by jets of water.

Large clinkers are retained on a grizzly over the sluice and are broken up with a sledge after the ash gate is closed. The ash is transported in the sluice by water admitted at intervals through high velocity jets to a temporary ash settling pit outside of the boiler house. The settling pit is 12 by 28 by 21 ft. deep with sides of steel sheet piling and is provided with adjustable baffles to assist in settling the fine ash. An overflow is provided for the water which discharges to the sewer. The ash is removed by a clamshell bucket on a crawler crane, loaded into trucks, and hauled to the ash dump.

### Turbo Generator

Fig. 8 gives a view of No. 1 unit in the foreground, and unit No. 2, under construction, in the background. The alternator is a 43,750 kv-a., 80 per cent power factor, 1876 rev. per min., 13,200 volts., three-phase, 62½ cycle machine, which is designed to operate later at 60 cycles. In addition to the main generator there is a shunt-wound shaft exciter rated at 250 kw., 250 volts d-c. overhung on the main shaft and beyond this and connected by means of a Fast flexible coupling is an auxiliary generator having a capacity of 1500 kv-a. at 80 per cent power factor and 460 volts, three-phase, 62½ cycle. The overall length of the turbo generator unit is 69 ft.

The turbine is a 13-stage Rateau impulse machine of 36,000 kw. capacity and drives the main generator through a Fast flexible coupling. It is a modified form of a turbine of lower normal rating of the non-bleeding type. The initial stages, however, have been opened up to pass the additional steam used in bleeding. Steam is supplied at a normal pressure of 390 lb. and a total temperature of 700 deg. fahr. Steam is bled at the 3rd, 5th, 8th, and 10th stages at full load pressures of 193, 99, 30, and 9 lb. absolute respectively. The turbine is designed for highest efficiency at 25,000 kw. load; and when bleeding steam at four points the unit can produce a net station send-out of 36,000 kw., which is the company rating of the machine. A considerably larger output can be produced by bleeding at the two lower points only.

### Generator Cooling

Both the main and auxiliary generators have closed re-circulating air cooling systems with two banks of coolers in each, one bank using condensate and one harbor water. The harbor water coolers are connected in parallel with the condenser circulating water system but have a roof tank connection for emergency. Condensate cooling is sufficient except for the summer months. The harbor water bank alone will provide sufficient cooling for maximum requirements.

Oil coolers are provided in duplicate, one using condensate and one harbor water, and arranged for individual or series oil circulation.

### Condenser

A 30,000-sq. ft., two-pass condenser is bolted directly to the bottom of the turbine exhaust casing and is supported partly by the casing and partly by springs on structural piers on the basement floor. The circulating water passages are so arranged that the cooler water leaving the air devaporizing and cooling section is returned in the second pass in the annular ring of tubes around the outside of the top section with which the exhaust steam first comes in contact. The shell is eccentric with the tube sheet, providing a steam belt which on one side extends to the hot well, which prevents excessive condensate depression.

The tubes are rolled into both tube sheets, a new feature of design that is discussed in other papers.

### Air Removal

Air is removed from a devaporizing section at the bottom of the condenser opposite the steam belt through two 10-in. openings which are joined in a 12-in. manifold leading to an 8-in. manifold on a three-element two-stage steam jet air pump located on the turbine platform. This pump is provided with a two-pass inter-condenser, containing 314 sq. ft. of surface and cooled by condensate only. Vent steam from the two top stage bleeder heaters and from the vent condenser of the deaerating heater is also condensed in the inter-condenser, the drips from which drain through a 12 ft. seal to the main condenser. The exhaust from the second stage jets is condensed in the after condenser. The combined capacity of the three elements on the pumps is 59 cu. ft. of free air per minute at 29 in. vacuum. Two elements at 17 cu. ft. per minute each are normally sufficient.

### Circulating Water

Circulating water from the Patapsco River passes through bar iron trash racks at the water front, under a submerged arch and through traveling water screens into an intake tunnel which will extend the length of the turbine room. Space is provided for four screens which are located outside and arranged for removal by a floating derrick. Each condenser is supplied by two motor driven pumps of 20,000 gal. per min. capacity each, both of which are required under full-load conditions in the summer. The tail pipe discharges in a tunnel common to all units, which is carried westward under the coal field to the water front. A steam jet ejector is used for priming the circulating water pumps.

### Hot Well Pumps

Condensate is removed from a 1000-gal. hot well by two motor-driven two-stage opposed impeller type hot well pumps, either of which is of sufficient capacity for full rated load operation.

### Bleeder Heaters

The 3rd, 5th, and 10th stage bleeder heaters, the evaporator condenser, and the after condenser are of the vertical closed type with four passes each. The construction of these heaters is shown in Fig. 9. The tube surface is made up of ¾ in. outside diameter, No. 14 gage Admiralty tubing, which is bent into hairpin loops with both ends rolled into a single tube sheet. The shells are of steel with hammer welded joints. Water boxes on the high pressure heaters for the first unit are of cast steel, but on the second unit will be of rolled plate. Steam is introduced in each case below the tubes and the baffles are arranged so that a vapor cooling chamber is provided to which the air vent connection is made at the side of the shell.

The 8th stage heater is of direct-contact deaerating type in which part of the bled steam is used in a section into which the condensate is sprayed through jets and part is used in another section similar to the open type feed heater in which trays are located and from which the air is removed. The pressure in the heater varies as the bled steam pressure varies. This heater is in the boiler house at an elevation of 80 ft. above the boiler feed pumps, which take their water from it. With a shell capacity of 6400 gal. it serves as a closed surge tank. The only condensate in the cycle which comes in contact with air is the condensed drip in the after condenser, which passes through the deaerating heater on its way back to the boiler.

### Evaporator

Make-up is supplied by a low heat level interstage evaporator of the vertical single-effect recirculating film type using city water as feed at a maximum rate of 10,000 lb. per hour corresponding to approximately 2½ per cent of the total full-load turbine steam flow. Fifth stage steam is used and the vapor is condensed in the evaporator condenser. The capacity may be increased by a by-pass connection of the vapor line to the 8th stage heater. The evaporator is located adjacent to the closed type bleeder heaters, under the turbine platform. Removable plates in this platform allow the handling of the shell and tube bundle of the evaporator as well as of the three heaters and two condensers with the turbine room crane.

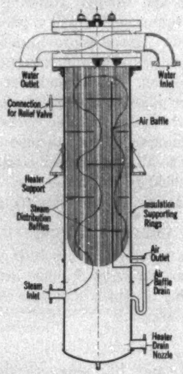

Fig. 9—Bleeder Heater of Hair-Pin Loop Construction

### Pumps and Water Storage

One five-stage motor driven boiler feed pump of 1000 gal. per min. capacity is provided for each main unit with one spare unit of the same size for each group of two units so arranged as to be available for either. A steam turbine-driven four-stage pump serving as a boiler protector only is installed with its suction connected to evaporated water and city water storage only and its discharge connected to the boiler feed mains.

Harbor water for miscellaneous cooling purposes is elevated from the screen well by two 800 gal. per min. motor-driven pumps in duplicate. A 15,000-gal. roof tank floats on the line. Two 1200 gal. per min. pumps furnish water from the same source at 125 lb. pressure for screen washing and ash sluicing. All of these pumps have bronze casings.

Condensate for make-up storage is removed from the cycle as it leaves the generator air coolers. A float in the 8th stage heater surge tank controls the amount removed. A tank of 21,000 gal. capacity at an elevation of 30 ft. above the turbine room floor receives this make-up, and further storage in two 15,000 gal. tanks is provided on the boiler house roof. Two 800 gal. pumps, arranged for either city water or evaporated water are used in this service.

City water is brought to the plant by lines from two sources. A float valve controls the supply to a 15,000-gal. tank on elevation 35, from which it is pumped to a 15,000-gal. tank on the roof.

### Piping

The single row of boilers parallel to the row of turbines makes for a very simple steam piping system. Steam is conveyed from single outlets on the Nos. 1 and 2 boilers to a four-neck manifold, from which is taken the No. 1 turbine lead and a tie to a second manifold. The second manifold is a duplicate of the first, with a connection from the No. 3 boiler and the No. 2 turbine in addition to a tie to a third future manifold. These manifolds are of seamless steel, forge welded, 25-in. outside diameter pipe. Boiler and turbine leads are 16 in. outside diameter seamless tubing designed for steam velocities of 9000 ft. per min. at rated load. Sargol joints, 600-lb. standard, with serrated faces are used throughout but valve flanges are made up with gaskets and not welded. An emergency closing valve was used on the No. 1 turbine lead but it will be omitted on the second unit. Motor-operated stop valves are used with additional remote control stations on the turbine platform.

One main and one auxiliary header is used on the boiler feed system with one feed line to each boiler from each header. All feed lines are of seamless steel extra heavy iron pipe size. Line joints and tee connections are all acetylene welded and fittings are employed only where welds cannot be used.

Lines conveying harbor water are of cast iron below the turbine room floor level, of extra heavy genuine wrought iron above the floor in sizes 2½ in. and larger and of standard pipe size brass in smaller sizes. Circulating water lines are of cast iron, atmospheric exhaust relief of fabricated steel plate welded inside and out at the joints, and all lines carrying condensate and city water are of standard steel. Welded joints have been used throughout wherever possible. The extensive use of welding has made it possible to group in a gallery space 11 ft. 6 in. wide by 11 ft. 4 in. high, with an unusual degree of accessibility, some 16 headers which will extend the length of the plant, only two of which are of sizes less than 6 in. diameter.

Eighty-five per cent magnesia insulation with a cement finish covered by 8-oz. Army duck is employed throughout. It is protected on high temperature lines by a layer of asbestos composition. Heater shells have a hard cement finish. Water boxes, turbine casing flange, and evaporator shell flange have removable blankets of asbestos fiber and cloth.

### CABLE TUNNEL

The generating voltage is 13,700 at the bus and about 13,300 at city sub-stations, the nominal voltage at the point of usage being 13,200. From the power house the energy is carried through the cable tunnel, shown in Fig. 10, to the isolated phase switch house by means of three 1,000,000-cir. mil lead sheathed cables per phase.

FIG. 10—VIEW OF CABLE TUNNEL LOOKING SOUTH

Insulation used on these cables is the standard for sub-station work—being 4/32-in. thick 30 per cent Hevea rubber and 10/32-in. Varnished Cambric. In order to prevent heating due to heavy currents in the lead sheaths, special phase arrangements were followed in pulling the cables into the ducts and the sheaths were grounded only in the centers, thus materially reducing the circulating currents.

### SWITCH HOUSE

The switch house shown in section in Fig. 11 has a basement and six floors. The side aisles of the basement are used for the high-tension potheads, this being the first and only place the phases come together. The center of the basement has been reserved for a 4000-volt distribution substation in the future. The first main floor has *C* phase equipment, the second carries *B* phase, and the third *A* phase. The operating mechanisms for the oil switches, bus disconnects, and pothead disconnects are located on the fourth floor together with the connections to the specially calibrated instrument transformers used on the water rate test circuits.

The fifth and sixth floors will extend over only a portion of the ultimate building and are used to house the control conduit boxes, station emergency lighting storage battery, and the operating room.

### CONTROL BOARD

The main control board in the operating room is a double board, semi-circular in shape. The center panels on the inner board carry the indicating meters and controls of the generators, while the end panels on either side control the outgoing feeders. The outside semi-circle carries the integrating watthour meters, relays, test switches, etc., for these various circuits.

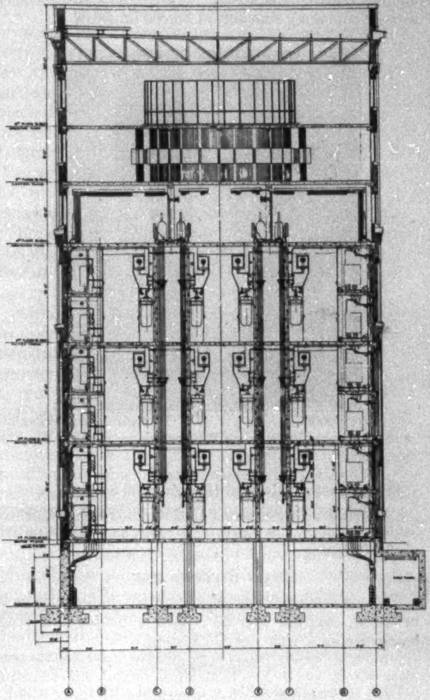

FIG. 11—CROSS-SECTION OF SWITCH HOUSE

There is another small board on the opposite side of the room which is used for the d-c. control circuits and the storage battery switching and charging.

### OIL SWITCHES

The oil switches on the outer ring bus have a rupturing capacity of 40,000 amperes, r. m. s. at 15,000 volts, based on the standard A. I. E. E. duty cycle, and they are built to operate on 15,000 volts, although standard 25,000 volt insulation is provided throughout. All generator and test bus tie circuits are equipped with 2000-ampere apparatus, while the outgoing feeders have 600-ampere oil switches and disconnects. Provision is made for the future installation of 4000 ampere bus sectionalizing switches.

The inner ring bus is equipped with switches having a rupturing capacity of 40,000 amperes on the generator and test bus tie circuits only. The feeder switches have a rated rupturing capacity of 30,000 amperes.

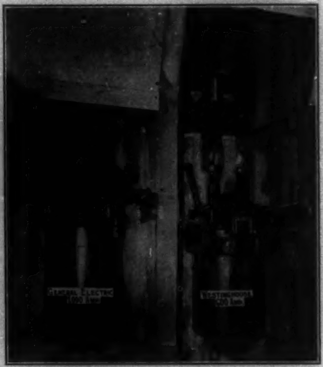

Fig. 12—2000-Ampere General Electric (Left) Generator Switch and 600-Ampere Westinghouse (Right) Feeder Switch

Fig. 12 shows a General Electric 2000 ampere generator switch on the left and a Westinghouse 600 ampere feeder switch on the right, both single pole for isolated phase mounting.

### Main Connections

The main connections of the switch house are seen in wiring diagram Fig. 13, which indicates two ring buses, giving a very flexible system.

### Reactors

Each three-phase feeder is equipped with three single-phase reactor coils, one on each phase floor, these coils having an impedance of ¾ ohm which limits a dead short circuit or ground to a maximum of 10,000 amperes, which is only one-third or in some cases one-fourth of the rated rupturing capacity of the switch. This same plan of limiting short circuits on feeders is employed in other generating stations and in substations and has resulted in greatly reducing interruptions and in maintaining bus voltage practically undisturbed by cable short circuits.

### Metering and Relays

On account of the strict isolated-phase system used it is necessary to connect all current and potential transformer circuits *YY*, thus necessitating 176-volt potential coils in some of the instruments. All neutrals of the current and potential circuits as well as those of the main generators are solidly grounded, while those of the auxiliary generators are left ungrounded.

A multi-element integrating watthour meter actuating a printometer totalizes the plant generation and gives regular demand readings hourly.

The outgoing feeders go to the city substations in groups of three, each group having selective differential relay protection by means of current balance in addition to the usual overload features. The machine oil switches are relayed to open only in case of a breakdown in the machine itself or in the leads to the switch house, differential protection being obtained with current transformers added to the neutrals. Overload on the machine circuit causes the field breakers to open and reclose, thus temporarily dropping load without cutting the generator off the bus.

### Excitation

Each machine has its own exciter bus which supplies excitation to the fields of both the main and auxiliary generators. Power is usually fed into this bus from the shaft exciter, but an emergency supply is available from a 200-kw. motor generator set.

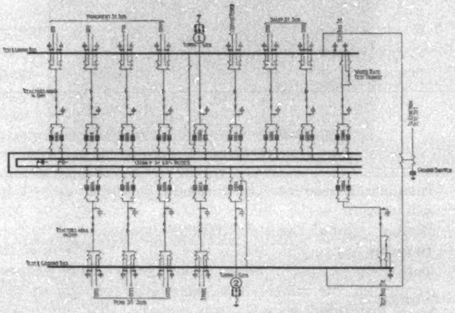

Fig. 13—One Line Wiring Diagram of Switch House, No. 1 and 2 Units

### 250-Volt Control

Throughout the plant is used 250-volt d-c. control. This voltage was adopted to conform with present day design. It effects a material saving in copper, compared to 125 volts due to the large currents necessary to handle present day equipment, and the long runs between the various parts of the plant. It also allows the d-c. generators to be rated as spare exciters, when they are of sufficient capacity.

### Lighting

Lighting in the main plant is a three-phase star system with grounded neutral. All circuits are run three-wire 120-208 volts through the panel boards with the neutral solid. In this way the failure of a single-phase transformer would only extinguish one-half of the lights on each circuit. The emergency circuits are automatically transferred from two-phase, three-wire, to d-c. three-wire when the voltage falls to 85. Return from the emergency d-c. supply to the normal transformer feed must be made by push button on the transfer contactor panel.

### 460-Volt Auxiliaries

Station auxiliaries are designed for 460 volts rather than 2300, because the lower voltage motors were lower in cost and kept in manufacturers' stocks. It was felt that the lower voltage was also somewhat safer and could be handled well by carbon circuit breakers. Carbon circuit breakers occupy less space than oil switches that would be required for 2300 volts. Their cost was lower and they are subject to inspection during operation as they are mounted on the front of the auxiliary switch board. The fire hazard with oil switches is also avoided.

### Automatic Combustion Control

The supply of fuel and air to the boilers and the removal of gas is controlled by Bailey automatic equipment which governs the speed of the forced-draft fans, induced-draft fans, and coal feeders. There is a separate control panel for each boiler. From this panel, the boiler operator controls auxiliary equipment and with the aid of signal lights and meters can tell at any time the operating condition as regards pressures, steam flow and electric power requirements for the various boiler auxiliaries. The electric circuits controlling the fans, feeders, etc., have been interlocked to shut down the equipment automatically in the event of failure of any part of the apparatus which might result in explosive mixtures in the furnace.

The induced and forced draft fan controls are the most unique in the plant. Due to the large size of the boilers and the high guaranteed rating of 550 per cent nominal rating, each of the boilers requires 1500 hp. for the four fans when operating at maximum rating. This is divided up as follows: two 200-hp. forced draft fans which introduce fresh air to the combustion chamber, and two 550-hp. induced draft fans which blow the hot gases up the stack.

The automatic combustion control used requires that the fans be able to follow very closely a predetermined speed curve of great range. To do this with a-c. motors a double speed primary is used, arranged for series connection for the first half of the range and for parallel connection the second half; large drums being used to regulate the secondary resistance for intermediate speeds.

The control for each fan consists of a low-speed secondary regulating resistance drum, a transfer switch for changing the number of poles by altering primary connections, a high-speed secondary regulating resistance drum, a balanced high-speed drum for the last five-speed points, a torque switch for starting, and the necessary circuit breakers and relays for interlocking and automatic protection. This combination of apparatus provides approximately 55 speed points for each fan.

In order to start up the fans it is only necessary to push a start button on the boiler panel which closes a latched-in relay. This places the fans in an operative condition. When the automatic combustion control calls for more draft the drums begin to rotate, the primary circuit breakers are automatically closed, the torque switches revolve until the motor starts up, and the drums are set on the desired operating point automatically. In the case of the induced draft fans, stack dampers are controlled by the same combustion control drive and a range of natural draft is utilized before the primary breakers close and the fans start. The speed range of induced draft fans is from 110 to 870 rev. per min. and on the forced draft fans the speed range is from 145 to 1170 rev. per min.

Primary air fans are controlled by manually operated secondary regulating resistance drums having 11 points, five of which are balanced. Their speed range is from 700 to 1750 rev. per min.

An elaborate system of interlocks has been provided to take care of emergencies in operating and to prevent situations which might cause an explosion of the powdered coal mixture in the boilers. Relay protection is provided to trip the fan circuit breakers on loss of 460 volts service. In case the two induced draft fans are tripped the two forced draft fans are automatically removed from the line to prevent the formation of positive pressure in the furnaces. If, at this time, the combustion control is still calling for mechanical draft, three of the four coal feeder motors are shut down. However, it is possible to operate the boilers at low ratings on natural draft and provision is made to prevent the shutting down of the coal feeders when operation is being carried on at low ratings. If the primary air pressure should fail three of the four coal-feeder motors are shut down and the steam aspirators are turned on. If positive pressure should occur in the furnace the forced draft fans and three of the coal-feeder motors are automatically shut down. Latched-in relays are used at the head of the various interlocking trains in order to prevent the shutting down of the fans in case of a failure of the d-c. relay supply circuits. The loss of control voltage will only prevent a change in speed of the fan motors, and will not cause them to shut down.

The coal feeder motors having an extreme speed range by means of automatic field control are direct current. Their bus is normally supplied by a 50-kw. motor-generator set with an emergency transfer breaker to operate in case of low voltage, throwing the load on to the main d-c. bus. The speed of these coal feeder motors is controlled by an automatic combustion control drive, which operates a gang of four field rheostats for each boiler. The motors are started and stopped by means of push buttons on the main boiler panels which control single step armature resistance starters. Interlocks have been provided as mentioned before to cut off three of the four motors in each group in case of trouble. These coal feeder motors are 5-hp., 250-volt, d-c., enclosed, and have a speed range of from 400 to 1600 rev. per min.

## BOILER FEED CONTROL

The 500-hp. boiler feed pumps are controlled by motor operated drums having 36 points and a speed range of from 1400 to 1750 rev. per min. The speed controls are arranged either for push button or automatic operation.

The automatic operation of each pump is controlled by the differential pressure between the pump discharge and the boiler drum. This differential, which is limited to a certain minimum, is varied approximately as the square of the load by a diaphragm on the regulator which is connected to the discharge duct of the forced draft fans. The process is selective by means of check valves in the case of the fan pressure and boiler pressure, so that the control is by the fan or boiler of highest pressure.

The 125-hp. condensate pumps have 24-point hand operated secondary regulating resistance drums with eight balanced points, giving a speed range of from 1400 to 1750 rev. per min. The 175-hp. circulators also have hand operated drums with a speed range of from 175 to 350 rev. per min. in eleven steps, five of which are balanced.

## CARBON CIRCUIT BREAKERS

Recent tests made by this company demonstrated that for low voltage, high current work, carbon circuit breakers and contactors performed satisfactorily in clearing the short circuits that might be imposed upon them at Gould St. From our point of view this was highly satisfactory, because such breakers and contactors are particularly well suited for inspection and maintenance. Being on open panel boards, heating or other troubles are readily discernible and contacts are easily inspected. Carbon circuit breakers are used exclusively on "essential" circuits—where interruptions must be reduced to an absolute minimum. Here it is necessary that a "latched-in" mechanism be used instead of depending on a holding coil, which is subject to failure. For the auxiliary generator, station service transformer, and other main feeders a type of circuit breaker was chosen with a mechanical trip-free arrangement, such that when closed in on a short circuit by remote control (solenoid operation) it would trip out the instant the short circuit was established. This feature of being trip-free throughout the entire stroke had to be developed especially for this job on the large 5000-ampere, three-pole breakers used on the station service transformers, and fan bus ties, although the smaller remote control and hand operated breakers were already available, so equipped.

FIG. 14—ONE LINE WIRING DIAGRAM OF A-C. AND D-C. AUXILIARY SERVICE FOR NO. 1 AND 2 UNITS

### 460-VOLT WIRING

Fig. 14 gives the wiring diagram for 460-volt auxiliaries. Separate operating buses are provided for the essential auxiliaries of each turbine and are supplied by the auxiliary generator. These buses are arranged in pairs with the ends overlapping so that the boiler feed pumps, primary air fans and coal feeder motor-generator set for each two units may, by means of double-throw knife switches, be operated from either bus. In addition each bus carries the circulator pumps, condensate pumps, and drip pumps of its own machine. It will be noted that the circulator and condensate pump feeds are arranged in pairs of one each. This necessitates the shutting down of only one motor of each class in case of a breaker tripping.

FIG. 15—VIEW OF STATION AUXILIARY SERVICE SWITCHBOARD

The essential auxiliaries are equipped with overload devices which function only on short circuits. In other words the circuit breaker trips or the CO relays are set to take the motor off the line only when the current exceeds the pull out torque value. Fig. 15 shows the 460-volt switchboard.

### STATION TRANSFORMERS

The station service transformers at present consist of three 1000-kv-a., 40-deg. cent. rise, 1250-kv-a., 55 deg. rise, or 1500-kv-a., one hr. overload rating single-phase oil-insulated self-cooled 13,200/460-volt transformers, connected delta delta. Relays are arranged so that an overload on this bank would trip off the coaling tower, the coaling bridge, and the preparation plant. The bank also has differential protection which trips the high tension oil switch as well as the low tension breaker, in case of internal trouble.

### COMMUNICATION

Communication throughout the plant is effected by a telautograph system having six stations, code calling by means of air whistles being used. There is also an intercommunicating telephone system which reaches strategic points in the entire plant as well as a number of Bell stations connected to the company's private branch switchboard for outside calls.

### INVESTMENT COSTS PER KW. CAPACITY

Throughout the design of the Gould St. Plant the object was to secure maximum reliability with minimum total costs per kw-hr. By total costs is meant not only operating labor and superintendence, maintenance, and fuel cost, but fixed charges on the investment. This criterion was used in the choice of apparatus, the cost of the apparatus being weighed against its ability to reduce production costs.

We give below a table of the actual cost of the first unit, and the estimated costs of three additional units; the estimated cost of the completed plant of 144,000 kw. being $88.26 per kw.

| | 1 unit (Actual) | 2 units (Est.) | 3 units (Est.) | 4 units (Est.) |
|---|---|---|---|---|
| 1. Investment cost as per Report of June 20, 1927 . . | $4,681,821 | $7,396,224 | $10,090,322 | $12,709,909 |
| 2. Capacity—kw. . . | 36,000 | 72,000 | 108,000 | 144,000 |
| 3. Cost per kw. . . . . | $130.05 | $102.73 | $93.43 | $88.26 |

The wide spread between the cost per kw. of the first unit and the cost per kw. of the completed plant is due to the many items included under the first unit, which are designed for the completed plant, such as, land, relieving platform for coal storage, coal handling, preparation plant, etc.

The capacities given in the above table are the net send-out capacity with four-stage bleeding.

Under two-stage bleeding conditions capacity is increased considerably and a net send-out capacity of 40,000 kw. is readily obtained and will be obtained in the event of need, for peak load conditions. Figuring this higher capacity the investment costs become as follows:

| | 1 unit (Actual) | 2 units (Est.) | 3 units (Est.) | 4 units (Est.) |
|---|---|---|---|---|
| 1. Investment cost as per Report of June 20, 1927 . . | $4,681,821 | $7,396,224 | $10,090,322 | $12,709,909 |
| 2. Capacity—kw. . . | 40,000 | 80,000 | 120,000 | 160,000 |
| 3. Cost per kw. . . . . | $117.05 | $92.45 | $84.08 | $79.44 |

The investment figures given include all expenses of every nature in connection with this plant, covering such items as preliminary engineering, old buildings used, interest during construction and during tuning up period, also a portion of the floating equipment of the company properly allocated to serve this plant.

### ACKNOWLEDGMENTS

Another paper is submitted at this meeting covering studies on design prepared by Messrs. Leilich, Follmer, Dannettel, and Fallon, to whom credit is given for the information in this general paper.

Mr. Penniman of the Company's staff is also presenting a paper on the operation of Gould St.

# Design Studies for Gould Street Generating Station

BY F. T. LEILICH[1], C. L. FOLLMER[1], and R. C. DANNETTEL[1]
Member, A. I. E. E. Non-Member Non-Member

***Synopsis.**—Developments in the central station art have been so rapid within the last few years that many of the recent outstanding stations differ considerably in major elements of design.*

*In the following, are briefly outlined, high points of the analyses upon which the principal features of the Gould Street design were based.*

THIS paper covers briefly the various studies and investigations upon which the Gould Street design was based. Load studies clearly showed the need of additional 62½ cycle generating capacity in 1927. As a result, a single unit station of approximately 35,000 kw. was authorized. The major features to be settled before equipment specifications could be prepared and detail design work started were: steam pressure and temperature; number and size of steam generators; type of firing—stokers or pulverized fuel; heat cycle or working heat balance; the most economic design of condenser; auxiliary drive—electric or steam.

## STEAM PRESSURE AND TEMPERATURE

The general trend of pressure and temperature was upward, as shown by Fig. 1, which was plotted from the specifications of 85 stations. Operating records of other plants were studied and most of the new stations visited, at which time design and operating problems were discussed with the engineers. Essentially the problem was to select a pressure and a temperature that would result in maximum reliability and minimum total costs.

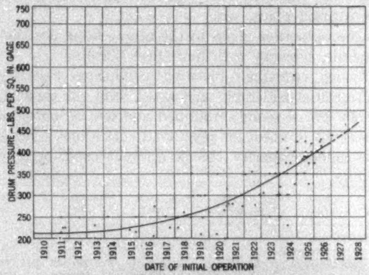

FIG. 1—TREND OF BOILER DRUM PRESSURE IN POWER PLANTS

Operating experiences with pressures up to 400 lb. and total steam temperatures up to 725 deg. fahr. were sufficiently extensive to show clearly that from the standpoint of reliability and operating difficulties these limits could be adopted for a conservative design. To obtain concrete figures showing the effect of pressure on costs and economy, detailed estimates based on a 40 per cent capacity factor, of a 250 lb.—700 deg. fahr., and a 400 lb.—700 deg. fahr. station were made. It is interesting to note that the estimated cost per kw. of the 250-lb. station was 4 per cent greater than for the higher pressure, and the over-all economy of the 400 lb. installation was six and one-half per cent better. Studies of relative costs of 600 and 700 deg. fahr. equipment showed that the improved economy of the higher temperature would justify the slightly increased cost of superheaters and added thickness of high temperature insulation.

A maximum drum pressure of 450 lb., with 725 deg. fahr. temperature at the superheater outlet was selected. This corresponds to 390 lb., 700 deg. fahr., at the turbine throttle. This temperature and pressure were selected after numerous conferences with the engineers of the various manufacturers and at the same time the possibilities of extension, using 1200 to 1500 lb. at the throttle of high-pressure turbines, exhausting at approximately 400 lb., into existing mains, were not overlooked.

## NUMBER AND SIZE OF STEAM GENERATORS

The boiler specifications called for working pressure in the drum of 425 lb. gage and total heating surface of 26,500 sq. ft. The bidders' guarantees covered operation up to 500 per cent rating, with 15 per cent $CO_2$, as it had practically been decided to use water-wall furnaces. The contract as awarded specified operation up to 520,000 lb. of steam per hr., which corresponds to approximately 550 per cent of rating, based on the total boiler and furnace heating surface. The trend of fixed and operating cost records of representative stations showed fixed costs as an increasing percentage of total costs and it was obvious that operating and kilowatt investment costs would be reduced if a small number of large steam generating units designed to operate efficiently over wide ranges of rating could be used. The experience up to that time indicated that water-cooled walls made it possible to operate at high ratings and over a wide range.

Load and operating conditions indicated that the

*Presented at Regional Meeting of District No. 2, of the A. I. E. E., Baltimore, Md., April 17-19, 1928.*

turbo-generator units should have capacities of from 30,000 to 40,000 kw. each. Numerous plant layouts were made, and based on these the ultimate capacity of the station was tentatively set at four units, or approximately 140,000 kw. Estimates of investment costs for both equipment and structure showed distinctly lower costs for a design based on one boiler per turbine. The boiler and furnace designers were ready to build and guarantee performance on equipment on this basis. With the cross-drum type of boiler, which was preferred by the engineers, additional heating surface could be economically obtained by increasing the length of the tubes and making the tube bank the maximum width consistent with drums having no girth seams.

### TYPE OF FIRING

Many of the newer plants were using pulverized fuel, but it was not obvious that the advantages of this type of firing were such that it should be adopted without careful study. Operating engineers of plants using the two types of firing were consulted and the merits of each carefully weighed. Proposals on stokers and pulverized fuel were obtained and economic set-ups, covering both fixed and operating costs, prepared. Although pulverized fuel investment costs were higher, when the merits of the two systems—tangible and intangible—were carefully considered it was finally decided to adopt the central system of pulverized fuel firing.

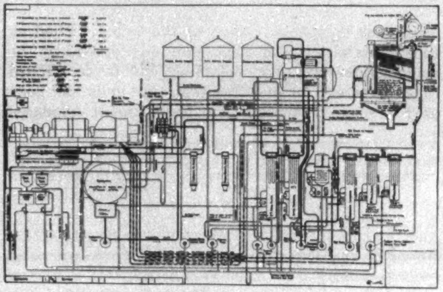

FIG. 2—FLOW SHEET REPRESENTING FULL-LOAD OPERATION WITH FOUR-STAGE BLEEDING AND 29 IN. VACUUM AT TURBINE EXHAUST

### HEAT CYCLE

A primary consideration was the selection of a heat cycle that would result in the lowest total cost, when both fixed and operating charges are included. Numerous set-ups were prepared, and economies calculated. Each showed that four-stage bleeding and air preheating would yield a greater return on investment than two or three bleeding stages combined with an economizer and preheater. The four-stage bleeding cycle has a further advantage of an approximate increase of 10 per cent capacity at only a slight drop in economy when operating under peak or emergency conditions with the two top-stage bleeders shut-off. In addition, for the machine under consideration a normal increase in capacity of approximately 300 kw. was possible, this being based on the power generated by the steam up to the first bleeding point, which steam by reason of limiting conditions of area in the lower stages could not have been used economically in the machine when designed for three-stage bleeding only. The foregoing advantages, and an economy increase of approximately 0.45 per cent by the use of four stages as compared to three, led to the adoption of the four-stage bleeder cycle.

Fig. 2 is a flow sheet showing the station heat balance for full load generation operating under 29 in. of vacuum.

The normal course of the condensate leaving the hotwell pumps is in order through the steam jet air pump inter-condenser, oil cooler, generator air cooler, tenth stage heater, after-condenser, eighth stage deaerating heater, boiler feed pump, evaporator condenser, fifth stage heater, and third stage heater to the boiler feed mains at a final temperature of 365 deg. fahr. Bypasses are provided individually for the oil cooler and the generator air cooler bank. Bypasses are also provided for the tenth stage heater and after-condenser as a group, and for the evaporator condenser and top-stage heaters as a group. Drips are cascaded from the top stage heaters to the evaporator condenser from which they are pumped into the condensate line leading to the eighth stage heater. Drips are cascaded also from the after-condenser to the tenth stage heater from which they are pumped into the condensate line leaving the tenth stage heater. The drip pumps are of the same type as the hotwell pumps, driven by slip-ring motors. Calculated feed water heater performances are given in Table I.

TABLE I
CHARACTERISTICS OF FEED WATER HEATERS

| Equipment | Lb. of water heated per hr. | Temperature deg. fahr. | | Water press. loss in ft. of water | Heating surface —sq. ft. | Terminal difference in deg. fahr. | Heat transfer in B. t. u. per sq. ft. per hr. per deg. fahr. mean temp. difference |
|---|---|---|---|---|---|---|---|
| | | In | Out | | | | |
| Third stage heater | 414,000 | 316 | 365 | 14 | 1,420 | 10 | 520 |
| Fifth stage heater | 414,000 | 279 | 316 | 15 | 1,565 | 7.5 | 515 |
| Evaporator condenser | 414,000 | 252 | 279 | 14 | 1,550 | 5 | 510 |
| Eighth stage heater | 340,000 | 204 | 247 | .. | .. | 0 | .. |
| After-condenser | 340,000 | 183 | 209 | 11 | 1,625 | 3 | 480 |
| Tenth stage heater | 310,000 | 92.5 | 182 | 11 | 2,000 | 5 | 455 |

Table II shows the calculated over-all B. t. u. per kw. hr. net station send-out. This is based on one boiler per turbine, auxiliary power 6 per cent of gross generation, over-all contingency factor 4 per cent, and throttle conditions 405 lb. absolute, 700 deg. fahr.

A turbine designed for non-bleeding operation was modified for bleeding conditions. Both the primary and secondary control valves admit steam to separate groups of nozzles which discharge through the buckets of the first wheel. This offered an advantage for bleeding at the third stage over designs where the secondary valve bypasses the first few stages. By increasing the steam flow areas in the first stages it was possible to admit sufficient steam for bleeding and still use the last stages as effectively in normal operation as for non-bleeding design. The non-bleeding machine was designed for 29 in. vacuum, but with the lower average vacuum of less than 29 in. expected at this particular installation, a greater quantity of steam is passed through to the condenser without increasing the leaving losses from the last stage and by reason of the power generated by this increased flow together with that generated by the additional steam admitted for withdrawal at the bleed points, the capacity of the turbine is considerably increased. A change from eleventh stage bleed-point to tenth stage gave an increase of 0.25 per cent in station economy.

TABLE II
B. T. U. PER KW. HR.—NET STATION SEND-OUT

| Load | 28 in. vac. | 28.5 in. vac. | 29 in. vac. |
|---|---|---|---|
| 35,000 kw. | 15,562 | 15,291 | 15,138 |
| 25,000 kw. | 15,103 | 14,707 | 14,356 |
| 15,000 kw. | 16,855 | 16,313 | 15,695 |

## CONDENSER

The average injection water temperatures throughout the year and the heat rejected to the condenser under various loads and exhaust conditions were the bases for the selection of the economic amount of condenser surface. Fig. 3 shows the relation between the exhaust temperature and the kilowatt increase in turbine output per degree of decrease in exhaust steam temperature. This method of analyzing turbine performance is described in the N. E. L. A. Prime Movers Committee Report on Turbines, December, 1926. The curve, (Fig. 4), shows the relation between injection water and exhaust steam temperatures for different load conditions and different areas of condensing surface. From the load duration estimate, injection water temperatures, and Figs. 3 and 4, the relative fuel economies of the different size condensers were determined. For these calculations, fuel cost was taken as 0.224 cent per kw. hr. In the final comparison, fixed charges were estimated at 16 per cent except on tubes, against which 30 per cent was charged, corresponding to about a 5-year life. It was found that 30,000 sq. ft. was about the maximum justifiable surface. This corresponds to 0.833 sq. ft. per kw. of generator capacity.

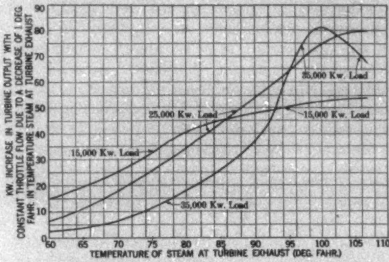

FIG. 3—GAIN IN TURBINE ECONOMY INCIDENT TO DECREASE OF DEG. FAHR. IN EXHAUST STEAM TEMPERATURE AT VARIOUS LOADS

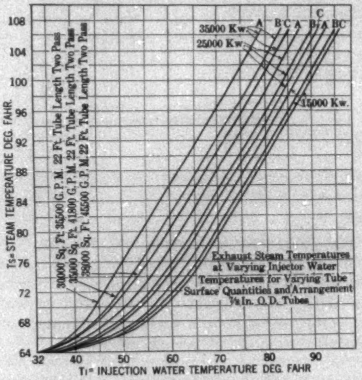

FIG. 4

It was essential that special effort be made to improve the purity of the condensate over that which ordinarily obtains in tide water plants; otherwise there would be no advantage in distilling the make-up, and the continuous operation of the boilers at high ratings would be seriously hampered. The point of attack was the leakage at the packed joints of the tubes. Floating tube sheets with rubber diaphragms as proposed by the manufacturers were not looked on with favor. Fixed tube sheets with tubes rolled in at both ends had been used in some instances in the Navy and it appeared feasible to adapt the principle to power plant service. It was found in tests made with an 18 ft. tube, set-up with the slight upward bow of 1½ in. at the center of its length between fixed plates, that repeated reversals of hot and cold water through it sufficient to give it the expansion between plates that would be encountered in service, produced no change in the structure of the metal of the tube, as seen under the microscope, and that the joints in the tube sheets remained tight. The tube was restrained in its vertical motion by the tube support plates, the holes in which were reamed to a special shape so that as the tube bends in expanding it has as much surface contact on the plate as possible. The shape of the expanded tube resembled a sine curve of about one and one-half cycles. The axial thrust of the tube against the sheets was as high as 425 lb. maximum, and at first it appeared that the staying of the sheets would be a difficult problem. On further analysis, however, the logic of eliminating all stay bolts presented itself, and the tube sheet layout shown in Fig. 5, in which all stay bolts are omitted and tubes rolled at both ends into fixed sheets, was adopted.

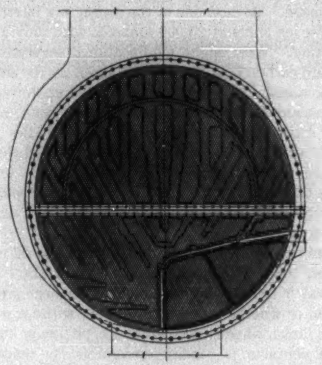

Fig. 5—Inlet End Tube Sheet Layout for 30,000 sq. ft. Condenser. (Note Question Mark Baffle for Guiding Water from Air Cooler Tube Surface to Outside Ring of Tubes in Second Pass

The manufacturer agreed to construct a condenser in accordance with this design with the provision, however, that the purchaser assume all responsibility for its success or failure.

### Auxiliary Drive

Electric drive was selected for the auxiliaries. Some of the factors influencing this decision were:

1. Elimination of small high pressure steam lines and exhaust lines.

2. Easier control of the heat cycle, as the steam requirements of turbine driven auxiliaries are not necessarily a direct function of the generator output.

3. Relatively high economy of shaft driven generators as compared to individual turbine drive. The steam per kw-hr. requirement for the auxiliary generator is the same as that of the main unit.

4. Flexibility and reliability of electric motors and their control.

The general tendency in auxiliary drive is shown in Table III, in which2 300, 440, and 220 volts were the prevailing a-c. potentials and 250 the prevailing direct current. Alternating current had been used in the greater number of installations and has the following advantages:

TABLE III
THE MAIN AUXILIARY CHARACTERISTICS OF CENTRAL GENERATING STATIONS

| Year of initial operation | Auxiliary voltage | | | Boiler feed pump drive | | | Circulating pump drive | | |
|---|---|---|---|---|---|---|---|---|---|
| | High 3000-2200 | Medium 660 -440 | Low 250 -110 | Turbine | Turbine and motor | Motor | Turbine | Turbine and motor | Motor |
| Other years | 0 | 1 | 2 | 2 | 1 | 0 | 3 | 0 | 0 |
| 1911 | 2 | 2 | 0 | 2 | 2 | 0 | 1 | 2 | 1 |
| 1912 | 0 | 1 | 0 | 1 | 0 | 0 | 0 | 1 | 0 |
| 1913 | 0 | 3 | 0 | 0 | 3 | 0 | 1 | 2 | 0 |
| 1914 | 0 | 1 | 0 | 0 | 1 | 0 | 0 | 0 | 1 |
| 1915 | 0 | 2 | 2 | 2 | 2 | 0 | 1 | 2 | 1 |
| 1916 | 1 | 1 | 0 | 1 | 1 | 0 | 1 | 1 | 0 |
| 1917 | 0 | 2 | 0 | 1 | 1 | 0 | 0 | 1 | 1 |
| 1918 | 1 | 3 | 0 | 2 | 2 | 0 | 0 | 2 | 2 |
| 1919 | 2 | 5 | 0 | 4 | 2 | 0 | 1 | 3 | 2 |
| 1920 | 3 | 0 | 1 | 3 | 3 | 0 | 2 | 2 | 2 |
| 1921 | 2 | 3 | 0 | 3 | 2 | 0 | 0 | 3 | 2 |
| 1922 | 2 | 0 | 1 | 0 | 3 | 0 | 0 | 1 | 2 |
| 1923 | 6 | 3 | 0 | 4 | 5 | 0 | 0 | 3 | 6 |
| 1924 | 12 | 3 | 0 | 6 | 8 | 2 | 0 | 2 | 12 |
| 1925 | 8 | 5 | 0 | 0 | 11 | 2 | 0 | 2 | 11 |
| 1926 | 6 | 0 | 0 | 1 | 4 | 1 | 1 | 1 | 4 |
| 1927 | 1 | 1 | 0 | 0 | 2 | 0 | 0 | 0 | 2 |

Note:

1. Since practically every station has electrically driven auxiliaries and all use alternating current except for a very small portion of the axuiliaries, such as stokers, it was assumed that all auxiliaries are driven using alternating current.

2. In cases where more than one voltage is used for the auxiliaries it was assumed that the larger auxiliaries, using the major portion of the auxiliary power, used the higher voltage.

3. The fans were, almost without exception, driven by motors.

4. Boiler feed pumps listed under turbine and motor drive are usually motor-driven with turbine-driven stand-bys.

5. The numbers under each heading indicate the number of stations in that class for the stated year of initial operation.

1. Available up to a capacity far in excess of auxiliary requirements, if transformers are used.

2. Relatively low costs of motors and control for applications with small ranges of speed control.

3. Absence of commutators (excepting brush shifting motors) and elimination of sparking, which is highly desirable in a pulverized fuel installation.

The selection of the most economical secondary voltage required extensive calculations and estimates in which were considered motor, control equipment, and installation costs, for voltages of 2300 and 440 and speeds from 575 to 1750 rev. per min., also space requirements and such intangibles as reliability, ease of inspection, etc.

A voltage of 2300 showed a saving in copper for long runs, but was considered undesirable because of the impracticability of inspection of the control equipment under load. The higher voltage motors are standard only in the larger sizes, and their use necessitates a low voltage supply for the motors below about 50 hp.

Fig. 6 is a curve of standard 60 cycle, 900 rev. per min. motor costs as of 1926. For squirrel-cage motors, it is interesting to note that the cost curves for the two voltages, plotted with motor costs as ordinates and horse power rating as abscissas crossed at 138 hp. For wound rotor motors having the same synchronous speed as the squirrel-cage motors, the curves for 75 to 150 hp. showed the 2300-volt motor to be more costly over the entire range. From the standpoint of the motor cost alone the 2300-volt equipment is economically advantageous only for the larger size motors. For the range of sizes to be used in this station the 440-volt equipment was less expensive in practically every case.

Estimates of the cost of distribution cable showed that the cost per ft. is about equal at 100 hp.; below this the cost advantage was in favor of the 440 to 460 volts. Cable costs were based on 440-volt lead covered cable with 600 volt insulation, and 2300-volt lead covered cable with 4000 volt insulation. When motor, control, and cable costs were added to the value of the space requirements, the 2300-volt system proved to be more expensive than the 440 volt. The final selection was 460 volts, 3-phase, 62½ cycles.

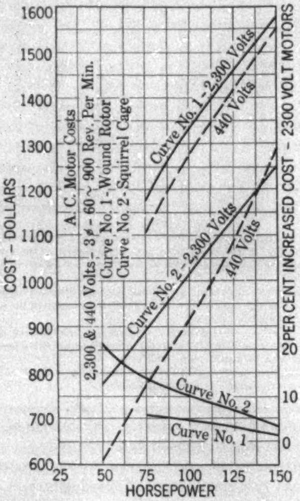

Fig. 6—Curves Showing Variation in Cost of Various Size Wound Rotor and Squirrel Cage Motors for 2300- and 440-Volt Service

For the auxiliary circuits it was desirable that oil breakers be eliminated and contactors or carbon breakers used. It was obvious that the circuit interrupting devices should be of sufficient capacity to handle short circuits, and in order to arrive at a basis upon which to prepare specifications a number of tests was carried out. The problem was put up to the manufacturers to furnish standard size contactors and circuit breakers rated up to 2000 amperes, which under test would handle repeated short circuits of not less than 20,000 amperes at 440 volts, 25 cycles, as the tests were to be made on 25 cycles. The contactors tested would not handle these currents, as after one or two operations the contacts had a tendency to "freeze." As a result of these tests, several of the manufacturers made modifications to their equipment, after which the contactors stood as many as five shots with practically no damage. In fact, one of the contactors interrupted about seven shots of 25,000 amperes with only a trace of pitting. With slight modifications, several of the standard carbon breakers handled about 20,000 amperes quite successfully. One feature insisted upon was that the breakers be non-closeable on short circuit, or trip free. Although the contactors handled the short circuits as well as the breakers, it was decided that the breakers were preferable to the contactors, for the reason that in case of failure of the holding coils, trip operated circuit breakers would not drop out, whereas contactors would.

Aside from the space requirements of the oil circuit breaker, there was the maintenance problem. There is no way of telling whether a breaker has been properly serviced or whether it needs attention, without removing the tanks, whereas with air break, pitting or burning of the contacts is readily discernible by inspection which can easily be made without dismantling the equipment. With a knowledge of the probable ultimate capacity of the station and the approximate maximum lengths of run and horse power of the auxiliaries, carbon circuit breakers were used on the auxiliary circuits with selected control equipment for handling the individual motor circuits. A control voltage of 250 volts, d-c., was used to eliminate the effects of a-c. disturbances on control apparatus and to insure quiet and more reliable operation of the contactors.

Auxiliaries were divided into two classes—essential, or those necessary for the uninterrupted operation of the turbine and boilers, and non-essential, or those such as pulverizing machinery—coal-handling plant and other equipment, a temporary shut-down of which would not interfere with the operation of the main unit and boilers. The essential auxiliaries are supplied with energy from the shaft driven alternator, the non-essentials from a bank of three 1000 kv-a., O. I. S. C. transformers. The arrangement is such that in the event of failure of the shaft driven alternator, the load is automatically transferred to the transformer bank. All auxiliaries are 460 volts, 3-phase, 62½ cycle, except the turbine room crane and the pulverized fuel feeder motors. These are supplied from motor generator sets, one running from the essential auxiliary bus, the other arranged to transfer automatically the load onto the transformer bank bus in the event of failure of the first motor generator set.

To reduce the voltage drop in the 460-volt bus, the copper in each phase was run in interleaved sections.

### COMBUSTION CONTROL

Based on the performance of stations operating with automatic combustion control, it appeared that monthly operating efficiencies that approached quite closely to test efficiency were possible. Proposals on automatic combustion control were analyzed, and calculations based on the guarantees and a study of performance in existing plants indicated that the increase in monthly efficiency would justify the cost.

On account of the wide range of speeds—8 to 1 on both forced and induced draft fans—double winding, 6-phase, secondary slip-ring motors were specified. A large number of speed points was necessary, and special control equipment consisting of drums and a motor-operated transfer switch for changing from the high to the low speed connection on the motor were installed. An excessive number of contactors would have been required to give the number of speed points specified. Also the cost of the control equipment using drums operated by the combustion control drive with provisions for manual operation and mechanical interlock between the drums was appreciably less than that of the contactor set-up.

## Discussion

For discussion of this paper see page 878.

# Operating Experiences at Gould Street Station

BY A. L. PENNIMAN, Jr.[1]
Associate, A. I. E. E.
and
F. W. QUARLES[2]
Non-member

*Synopsis.—This paper deals with experiences in connection with the starting up and the initial operation of a steam-electric generating station, located at Baltimore, consisting of large cross-drum, sectional header, water tube boilers fitted with water cooled furnaces which are fired by pulverized coal. The plant operates at 450-lb. pressure with 725 deg. temperature steam, the turbines being fitted for four-stage bleeding. All auxiliaries are motor driven, the power being supplied either from direct-connected auxiliary generators, or from the main station bus bars through step-down transformers. This paper attempts to describe the major difficulties that were encountered in placing the plant in operation and outline the methods used in their elimination.*

THE first cost of a power plant in any given location under the physical conditions existing at the site chosen, is largely a question of the fullest use of materials and equipment. This makes it desirable to use the smallest number of units of equipment of the largest permissible size, operated at the maximum allowable ratings. The auxiliary equipment must be carefully selected, with a view to maximum reliability, so as to permit of the installation of a minimum amount of spare apparatus. The installation of the equipment thus chosen, in order to use a minimum amount of space consistent with ease of access for operation and adequate maintenance, will result in the most economical balance between first cost and operating labor and maintenance costs. The actual manner in which this scheme has been carried out in the Gould Street Station of the Consolidated Gas, Electric Light & Power Company is described in two other papers.[3] It is the purpose of this paper to present some of the actual difficulties encountered during the initial period of operation.

### OPERATING PERSONNEL

The Gould Street plant represents our first experience in the burning of pulverized coal. For this reason, we were somewhat handicapped in the selection of an operating crew; especially so, since we considered it highly desirable to have as operators men who had been under observation for a sufficient length of time to satisfy us with regard to their fitness. Several months previous to the time that the first section of the Gould Street plant was scheduled to be ready for operation, certain men who were judged to be able to adapt themselves easily to the operation of pulverized coal equipment were selected from the operating organization. Also certain other men were employed and given some operating training at our Westport stoker-fired plant.

### COAL HANDLING EQUIPMENT

That equipment which we have classed as coal handling equipment consists of the coal hoist, Bradford breaker, barge haul and five conveyer belts, the second belt being provided with an airplane tripper for unloading to the coal storage yard, also with a hopper to receive coal reclaimed from storage. The pulverized coal transport equipment is considered separately.

Troubles which have developed in the coal handling equipment have not resulted in any great amount of inconvenience. Of major importance was the failure of some parts used in propelling the airplane tripper and its unloader belt, the drive being from the main conveyer belt by means of gearing and clutches. One of these failures resulted in a runaway condition with considerable damage narrowly averted. The weakness was inherent in the design and was obviated by changing the drive over to a cable haulage arrangement actuated by a separately controlled motor.

### COAL PREPARATION EQUIPMENT

While a hammer mill, which is herein designated as a secondary crusher, is located between the second and third conveyer belts, we really consider this equipment a part of the coal preparation equipment. With the original arrangement of plates and hammers the capacity of this hammer mill was such that coal was piled up at its inlet when the coal hoist was operated at capacity. Readjustments were made, not only because of the hammer mill's limited capacity with its original adjustment, but also because it was thought that with somewhat coarser coal some difficulties with our grid driers could be eliminated or at least alleviated. After these changes were made, the capacity was increased, but the drier difficulties were not helped to any great extent. It was finally decided to by-pass the hammer mill completely, which enabled us to get better flow through the grid drier with little arching of the coal but, of course, placed a heavier duty on the pulverizing mills.

A pulverized coal system handling wet coal is subject to many ills, and it is difficult to obtain proper flow at many of the points where gravity is the moving force. Very unsatisfactory grinding is obtained with wet coal; after the coal is ground, some of it forms a pasty mass and sticks at almost every conceivable point; a mucky

mass very often collects in the mill, choking up the air passages; vent lines become choked; cyclone separator discharge lines become plugged; transport pumps and lines become plugged; the coal cakes in the pulverized coal bins; arches over the feeder screws at the boiler, causing burners to become extinguished; and even the burner pipes become so choked that in many cases it is necessary to take pipes down for cleaning, as the rapping on the pipe is often ineffective. There is also much difficulty from irregular feeding of the coal to the furnaces, which greatly reduces the furnace efficiency.

The steam-heated grid-type driers originally installed were found to be inadequate for our conditions. As already explained, the delivery of fine coal to the drier resulted in arching and inability to get the coal to flow through the drier. There was also additional trouble due to the pulling along of considerable coal by the air used to remove the moisture. A large amount of air is necessary and while it was put through a cyclone separator, the separation was incomplete, causing a considerable loss of coal. The coal recovered in this cyclone separator was discharged into the hoppers of the transport pumps. There was the additional objection that much of this coal was coarser than desired. Some of the drier grids were removed to better these conditions. While the feeding was bettered, the drying of course was less complete.

Furthermore, the amount of moisture removed was not so great as was necessary for the satisfactory milling and handling of the coal. Failure in this respect caused other means of obtaining the desired result to be considered. We believed that the most reasonable scheme would be that of drying the coal while in a finely divided state in the air circulatory system of the pulverizing mills, as it should give up its free moisture very readily. Due to the relative locations of the mill house and boiler room, it was not feasible to use stack gases for supplying the heat required, or to use the air vented from the mill system for primary air. Accordingly it was decided to heat the make-up air by means of high-pressure steam, so as to obtain the maximum temperature, thereby permitting us to supply the necessary heat with a minimum of air. This permits of using apparatus that is much more compact and reduces to a minimum the amount of fine coal that is lost in the vented air. The mill drier is not effective in drying the coal until it enters the mill and this, of course, does not help the flow of coal to the mill. High moisture, however, has caused no appreciable difficulty in feeding the mills, since the grid driers have been removed. The mill drying system is performing very satisfactorily and has practically eliminated the many annoyances incident to wet coal. In regular operating practise the mill drier has been successful in reducing the moisture content of the coal from 6 per cent entering the mill down to 1.7 per cent leaving the mill.

The air washer as originally installed for use with the grid type driers did not remove the coal dust to a sufficient degree. It was also inadequate when the mill type drier was put in commission. In order to obtain satisfactory removal, it was necessary to increase both the amount of steam and water used. At the present time, approximately 1150 lb. of steam and 2900 gal. of water are used per hour, with a dust concentration of about 0.8 grain per cu. ft. of air entering the washer, the amount of air handled being approximately 1240 cu. ft. per min.

On the whole, the pulverizing mills have performed very satisfactorily, although, of course, there is considerable wear of the grinding rollers and bull ring of the pulverizing mills, and of the blades and wearing plates of the mill exhausters. These mills, (designated by the manufacturer as of 20-tons per hr. capacity), have pulverized at an average rate slightly in excess of 24 tons per hr. each, the coal leaving the mill having an analysis about as follows:

| | |
|---|---|
| Moisture | 0.76 per cent |
| Volatile | 25.28 per cent |
| Fixed Carbon | 63.76 per cent |
| Ash | 10.20 per cent |
| Sulphur | 2.02 per cent |
| Amount through 200-mesh sieve | 74.2 per cent |
| Amount through 100-mesh sieve | 89.4 per cent |
| Retained on 40-mesh sieve | 0.4 per cent |

At times there has been some difficulty experienced due to coal hanging up in the cyclone separators or in faulty delivery to the hoppers of the transport pumps, because of improper functioning of the flappers of check valves or the choking of vent lines from hoppers to suction pipes of mill exhausters. One other difficulty was the collecting of a mucky mass of coal and water in the chamber of the mill that receives the air returned from the cyclone separator. A muck collecting pocket installed on one of the mills served to alleviate this condition somewhat. However, the better drying obtained when the mill-type drier was installed eliminated all trouble of this nature.

### Coal Transport System

There was considerable trouble with the operation of the pulverized-coal transport system when the plant became active. Most of the difficulties resulted in the plugging of transport lines which, being new and rough, were accredited with the responsibility for part of the troubles. The starting up of this system occurred during cold weather and this, in conjunction with the faulty performance of the driers was responsible, no doubt, for the greater portion of the plugging. Also, the size of the hoppers above the transport pumps was thought to be too small for even delivery to the screws of the pumps and partially responsible for the pumps plugging. Accordingly, they were increased in size by adding height with filler pieces having rectangular openings to conform to the hoppers. It was discovered that considerable water collected in the cylinders of the pumps after being shut down several hours. Keepnig the pumps drained was the logical answer to this difficulty. Increasing the air pressure on the nozzles of the pumps also helped to keep the boilers supplied with coal. Later, when the transport lines were worn smooth and the mill drier system was in service, trouble with the transport system practically disappeared.

Coupled with the difficulties of pumping the coal was the difficulty of the sticking of the transport line switching valves. This was alleviated somewhat by applying brass liners to the valves. This has not been an absolute remedy, as it is necessary to operate the valves frequently and even then, to dismantle them occasionally for complete cleaning. A careful analysis of the factors involved is now under way and it is hoped that this will result in eliminating any abnormal routine operation of the valves to prevent their sticking.

### PULVERIZING COSTS

The amount of power used in the grinding and transporting of the pulverized coal averages approximately 19.6 kw-hr. per ton of 2000 lb. The expenditure for the maintenance of pulverizing equipment has been approimately 13.9 cents per ton.

### BOILER ROOM

The greater amount of effort has been put forth in tuning up and making structural changes in the boiler room to approach or exceed design conditions. While efforts have been made to hasten the process, at this date, February 10, 1928, there are several matters that have not been brought to a satisfactory state.

At the outset considerable difficulty was experienced with poor feeding of the coal due to insufficient drying and condensation on the walls of the bunkers. It frequently became necessary to empty a bunker of the coal which would flow; then have men enter the bunker and scrape down the pasty masses of coal which cling the walls and arch over the feeder screws. This condition was eliminated almost entirely by the mill type drier when it was put in operation. Since our early experiences, No. 1 bunker has been covered with heat-insulating material and an investigation has been made on No. 2 bunker by forcing preheated air over the coal from one end to the vent at the opposite end to reduce the humidity of the air over the coal. The use of hot air results in less condensation on the walls, but also in an increase in the amount of coal lost out of the bunker vent. A combination of heat insulation with the use of hot air would probably give a still better feeding performance.

With the coal-feeding equipment originally installed, it was impossible to reach the maximum designed capacity, part of the fault being insufficient motor speed. However, sufficient coal could not be supplied after the motor speed was increased to that designated. New screws, having a considerably greater capacity, were furnished for one boiler. These screws caused flooding to take place at lower ratings, resulting in very dense smoke and, in one or two cases, in the loss of much coal to the ash hoppers. Also, these screws had so much capacity that it was considered advisable to abandon them and hob out the original screws. Flooding also took place on these modified screws and to eliminate this, spring-loaded disks were applied to the discharge end of the screws to provide a uniform resistance to the coal being fed. These very successfully reduced the pulsations experienced with the feeders having greater capacity than the original.

The controls of dampers in the various ducts were originally unsatisfactory, in that it was possible for sudden changes to occur if the hand slipped on the operating chains. In the case of the primary air system, a damper got out of control and was responsible for an explosion occurring in the furnace of number one boiler, this explosion resulting in bulging of the steel casing and the bending of several side-wall tubes. By applying worm wheels and sectors to these dampers, the control has been made positive and easier to manipulate.

In order to guard against future explosions displacing the furnace sides, a horizontal steel buckstay was applied around the middle of the furnace for additional strength, as it was assumed that the air and gas passages should furnish sufficient relief for the expansion of the products of combustion resulting from such explosions. The boiler control, also, was provided with some features to eliminate some of the provoking causes of explosions. Furnace contactors were provided to trip out three of the four coal feeder motors per boiler on the occurrence of excessive furnace pressure. Primary air pressure contactors were arranged to trip out the same three feeder motors and to turn on the steam to the burner aspirators on the occurrence of low primary air pressure. The forced draft fan control is arranged to trip if both induced draft fans are tripped. Since these modifications have been made, no occasion has arisen necessitating their functioning.

Changes have been made in the burner design with respect to what is termed the tertiary air, *i. e.*, the heated air which is forced downward around the burner nozzle. These changes have been made with the idea of producing a longer downward sweep of the flame with less and hotter primary air. The present indications are that the new arrangement is very beneficial.

Experimental observations were resorted to in order to obtain a better distribution of air across the furnace. The number of port openings in the front wall was substantially reduced which, by proper selection of the ones to be closed off, improved the distribution, produced greater turbulence, and also made available a higher tertiary air pressure. It was then possible to exercise more control over the tertiary air.

The spring-loaded dampers governing the flow of secondary air to lanes in the front wall have performed unsatisfactorily at times, and it has been necessary to provide hand-control to those governing the air admitted by the four uppermost lanes. It is now considered desirable to have all of the spring-loaded dampers operated by hand from the main boiler floor.

Some difficulties have been encountered with slagging of the lower rows of boiler tubes. This slagging usually occurred after the boiler had been carrying about 400 per cent rating continuously for 48 hours or longer. Little trouble was experienced when less load was carried at night than in the daytime, and it has been noticed that much slag which had accumulated when operating at high rating, fell off when the rating was reduced for several hours. On one of these occasions when a high rating had been maintained for longer than 48 hours, an attempt was made to cause the slag to drop by increasing the excess air, but this apparently had little effect. A shot gun was fired at the slag but was found to have negligible effect. One proposal advanced to prevent this trouble was to remove every other tube in the bottom row of boiler tubes, which would mean that the spacing of this bottom row would then be approximately the same as that of the water screen and, consequently, slagging would be greatly reduced. The boiler manufacturer has recommended against removal of these tubes and, instead, suggests removing every other tube in the lower row and installing deformed tubes which would have a drop of 7 in., thereby accomplishing the same result with no loss in heating surface.

The air heaters are arranged with straight vertical flue gas passages and U-shaped air passages, the air entering and leaving on the same side of the heater, thereby providing very unequal resistances to flow in the air lanes. The result of this was a wide spread in the air temperatures leaving the air heater, there being about 200-deg. fahr. temperature difference between the top and bottom of the duct discharging air from the heater. A deflecting-type baffle was applied to guide the air towards the lanes having the longer paths. Another scheme which was also experimented with, consisted of adding resistance at the air inlet to the shorter paths, the increased resistance to flow of air being obtained by the application of metal strips. The two schemes did materially help the situation and were of about equal merit, although neither attained the desired result. Both schemes are objectionable from the standpoint of power loss caused by the increased duty placed on the forced draft fans. The air heater manufacturer is now taking necessary steps to improve the performance of this apparatus.

The bearings on the primary air and induced draft fans are of the ring oiled type provided with an integral oil cooler built into their bases to eliminate the necessity of separate oil pumps for the circulation of the oil and also to permit the use of harbor water for cooling. There was some trouble from the leakage of water into the oil reservoirs which was eliminated by a slight change in the design of the coolers.

The induced draft fans are of the plate-type because of the high duty imposed by the requirement of handling 135,000 cu. ft. per minute of 450-deg. fahr. gases against a static head of 15.8 in. of water. These fans have given excellent service except for some slight vibration due to the bearing pedestals being somewhat light. This has been corrected by the application of bracing. Two failures of an induced draft fan motor have occurred, the reason for which cannot be ascribed to overload or faulty control. The first failure was of the north motor on No. 2 boiler. This motor was removed for repairs and was replaced by No. 1 south motor. The repaired motor, when returned, was placed at the former location of No. 1 south motor. Soon after this, the repaired motor failed. This motor was again repaired and has been operating satisfactorily for some time.

Five failures of fin tubes constituting the back furnace wall have occurred. These tubes have all failed in the same manner and almost at the same spot; namely, the outside of the top bend of the rear wall tubes near the sides of the furnaces. In one case, a large bulge was noticed before an actual rupture occurred. The water circulation is to be investigated to determine whether or not there is considerable difference in rapidity of water circulation in different parts of the back wall. The obtaining of this information will no doubt make possible a satisfactory analysis of this condition.

Because of the high rating for which these boilers are designed, it was necessary to supply two 6-in. feed-water regulating valves. It was found that the thermostatic tubes of the feed-water regulators were not sufficiently powerful to operate the valves properly. New pistons were designed by the manufacturer in an effort to reduce the friction which was apparently caused by water flow, since the friction was quite low when no water was flowing through the valves. The new pistons did not prove entirely satisfactory and attention was directed toward the use of hydraulic power utilizing the thermostatic tube to actuate only a pilot valve. As an experiment, one such valve was fitted with a hydraulically operated relay mechanism. The operation was so much more satisfactory that the manufacturer equipped all the regulators with hydraulic operating mechanisms. With this arrangement, there is the additional advantage that the slope of the thermostatic tube can be lessened to speed up the response of the regulator.

Soon after starting the plant, it was determined that the moisture content of the steam leaving the boiler drums was higher than desirable. The boiler manufacturer has developed and installed a new type of baffle which has produced excellent results. The curves in Fig. 1 show, graphically, how great the improvement has been. This improvement should be of much benefit in the maintaining of cleaner surface on the interior of the superheater tubes, since the moisture, of course, carries solids in solution. It also will reduce the duty on the superheater for a given temperature of steam leaving the superheater.

The plant has operated for a large portion of the year 1927, with lower superheat than the design value. It was held advisable to delay the raising of the steam temperature until other apparatus which would influence the result had been tuned up. Just recently the baffling of the gas passage at the superheater has been changed to give the desired steam temperature. The remaining feature to be reckoned with is the pressure drop of the steam through the superheater, this being approximately 35 per cent higher than expected. Since it reduces the pressure available at the turbine throttle with a given boiler drum pressure, this pressure loss results in a diminution of turbine capacity, thereby limiting plant capacity. The manufacturer has considered the possibilities of reducing this pressure loss to the desired value and is taking the necessary steps to eliminate this difficulty in the near future.

As to the matter of combustion control, several difficulties were experienced in the burning out or breaking down of coils and grounding of wiring. Discharge resistances were provided to lessen the inductive kick from the coils, and wire with varnished cambric insulation was used in the control boxes to withstand the oily atmosphere. Some trouble has also been experienced with the motors in the control boxes grounding, the grounding usually occurring on the brush rigging. Now it is planned to arrange the drive so that the motors may be placed outside. Some gears have been broken, a key sheared, and chains broken, the chains being used to interlock the various drum controllers of the fan motors. Because of the necessity of controlling two 550-hp. pole-changing induced-draft fan motors and two 200-hp. pole-changing forced-draft fan motors, all of the wound rotor induction type, the drive necessarily has quite a task to accomplish, the pole changing feature of the motors contributing some complication on account of the necessity of providing overlap.

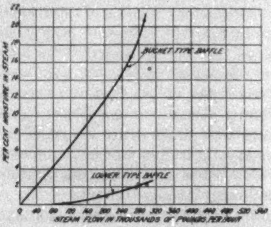

Fig. 1—Steam Quality Gould Street Boilers

The combustion control is normally set to maintain 15 per cent $CO_2$ averaged across the section of the boiler gas outlet. This setting is interfered with to some extent by a variation in feed water temperature. This is particularly so if the two higher pressure feed-water heaters are cut out of the circuit at 20,000- to 35,000-kw. load on one boiler. An attachment has been designed to quickly correct the meter for this condition and is being installed. The combustion control which we have installed is not suitable for quick changes in load, this having been demonstrated several times. It is our usual practise to operate on semi-automatic control for the quick changes in load which can be anticipated, such as the noontime drop and the morning pick-up.

There are eight 4½-in. high lift safety valves on the drum, and two on the superheater outlet of each boiler, each drum valve having a relieving capacity of 52,500 lb. per hr. and each superheater valve 35,000 lb. per hr. While these valves have not been tested for relieving capacity, two occasions have arisen when the entire plant load has been lost in which the safety valves relieved a total of 380,000 lb. per hr. satisfactorily. One of these occasions was when an air drill penetrated the high-voltage leads from the main generator, causing the differential relays to trip out the oil switch and field breaker, the other when the throttle valve of the main unit became unlatched. The leakage and maintenance of these valves has been very slight and, as a matter of fact, has not been any higher than has been experienced at the Westport plant on 200-lb. pressure service.

There are three ash gates per boiler, 41 in. by 56 in., actuated by oil operated cylinders which at times have refused to move due to friction, distortion, and failure of cast iron plates. In certain places where two ferrous materials rub on one another, one of them has been replaced by non-ferrous material, clearances have been increased, and the cast iron support plates have been reinforced with steel. The result has been almost complete elimination of the sticking difficulties.

## TURBINE ROOM

Since No. 1 turbine has been placed in operation, few troubles have been experienced with it. One of these has been the sticking of the primary control valve stem. This stem was made of "Ascoloy" and slides in a Monel bushing. These two metals apparently are not very satisfactory for sliding contact. The Ascoloy stem was replaced with one of medium carbon machinery steel and the bushing enlarged to give a greater amount of clearance, the packing being relied upon to serve partially as a guide. It is contemplated that an Ascoloy stem will again be used but with a cast iron bushing so contained in a steel cage that the cast iron will not be able to break up and go through the turbine. One difficulty which was experienced soon after the turbine was started up the first time was undesirable vibration of the throttle and control valves. This was remedied by the elimination of undue play at certain points and the redistribution of the weight of the pipe, control, and throttle valves among several hangers.

The main condenser, while of somewhat radical design in that the tubes are rolled into the tube sheet at both ends, has given but little trouble. The noticeable leaks which have occurred have been very few. In spite of the fact that the circulating water is high in salt content, we have been able to maintain the solids in solution in the condensate at a very low value. Computations made before the plant was put into commission indicated that if the leakage was as high as usually obtained with packed tube condensers, it would be necessary to blow down the boilers very frequently, or continuously, in order to maintain the boiler water concentration at as low a value as was considered desirable. The following figures are indicative of the purity of the condensate as usually obtained:

Total solids.......... two parts per million.

Electrical Resistivity..1,000,000 ohms per cm-cube.

While the dip cells used in determining the electrical resistance of the condensate are subject to erratic behavior at times, the electrical resistance characteristic has been of great help in showing relative performance, because of the rapid change in resistance for a small change in the amount of leakage. Only one leak of consequence has shown up, this one apparently being due to a condenser tube not being rolled in at one end, the flare serving to keep the leakage down for a long time.

The circulating pumps originally furnished required too much power because of the water quantity pumped exceeding the design value and, in order to lessen the load on the motors, it was decided to turn down the impellers.

One trouble which has been had with the steam jet air pump inter-condenser has been the erosion of tubes from the discharge of steam from the pipes used to vent some of the bleeder heaters. Some tubes were removed and a baffle installed to decrease the velocity of the steam hitting the tubes.

The difficulties experienced with the closed bleeder heaters has been confined mainly to those under boiler feed pressure, the most annoying one being the leaking of gasketed joints. Some of this was a result of poor machining. Re-machining and the use of different gasket material has eliminated this annoyance almost entirely. One other source of annoyance has been the leaking of a porous, cast steel, water box which is to be replaced by the manufacturer. The eighth-stage bleeder heater is of the deaerating type and has given no operating troubles, and has delivered water having less than 0.05 cu. cm. per liter of oxygen.

As originally furnished, the evaporator, while its capacity was all that was expected, did not produce a distillate measuring up to the standard required. Considerable experimental work was required before this standard was attained. We were fortunate during this time in having a boiler operating in the old plant supplying steam for heating purposes. Thus, the heating boiler acted as an evaporator and the heating system as an evaporator condenser. The quality of the water obtained in this manner was good, and the amount was great enough for make-up purposes. The changes in the design of the evaporator were completed at about the time that the heating season ended. The evaporator is now producing water of following quality:

Total solids.......... 3.4 parts per million.

Electrical Resistivity..227,000 ohms per cm. cube.

With low condenser leakage and water of this quality, we have been able not only to hold the boiler water concentration to a low figure but have not been required to blow down the boilers at all on account of concentration, the concentration not having exceeded 500 parts per million.

While the boiler feed pumps are boiler auxiliaries, we are treating them under the head of turbine room equipment, since they are actually in the turbine room and are connected in between the low- and high-pressure bleeder heaters. The motor-driven boiler feed pumps have given but little trouble structurally. On one occasion there was a cessation of pumping which appeared to be due to vapor binding. This was ascribed to hot water discharged from the evaporator condenser drip pump being fed to the suction side of the boiler feed pump. While there was an economic advantage to the scheme from the standpoint of heat efficiency, it was considered to be outweighed by the demand for safe operation and, accordingly, this water was delivered to the eighth stage heater. Since then no further trouble of this nature has occurred. A shifting of the impellers and balancing drum occurred on the emergency steam driven boiler feed pump. This was apparently due to the wearing sleeves turning enough to allow the shift to take place. When repairs were made these sleeves were driven up hard and locked so that this trouble is not expected to occur again.

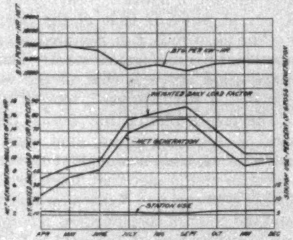

Fig. 2—Monthly Performance of Gould Street in 1927

### Over-All Performance

Whereas the plant delivered power to the bus for the first time on January 4, 1927, the amount of generation for the first three months was comparatively small, because of the decision to concentrate attention on those details which most affected the dependable operation of the plant. For this reason, these three months have been neglected in drawing up Fig. 2, which graphically illustrates the amount of generation per month, the average weighted daily load factor and B. t. u. consumption per kw-hr. of net sendout. The amount of generation reflects not only the tuning up of the plant but also the manner in which steam generation at Baltimore is affected by the river flow at the hydroelectric plant of the Pennsylvania Water and Power Company from whom we purchase quite a considerable amount of power. Two curves are shown on Fig. 3, one of which is that of the predicted performance of the plant in B. t. u. required per net kw-hr. of station sendout plotted against weekly load factor in per cent; the other curve is that of the weekly performance in B. t. u. actually used, plotted in the same manner. The points plotted for actual performance show quite a wide variation, not only because of the changes being made in the plant during the year, but also because of the fact that there are large coal storage spaces between the point at which the coal is weighed and the point of consumption, a comparatively small error in estimation of the coal in these spaces causing a much larger error in the consumption figures, the greatest error occurring when the consumption is least. It is expected that the installation of automatic coal scales to weigh the coal entering the mills will greatly decrease this error, since the effect of an error in the estimation of the raw coal bunker will be eliminated from the result, the pulverized coal bunkers then being the only storage space affecting the accuracy of the consumption figures. The monthly figures are somewhat more accurate since the amount of coal used is about four times larger and the error introduced by bunker estimates is thereby made one-fourth as much. It is expected that the predicted performance will be approached very closely.

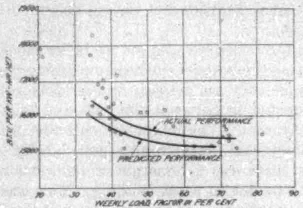

Fig. 3—Relation of Actual to Predicted Performance for Gould Street in 1927

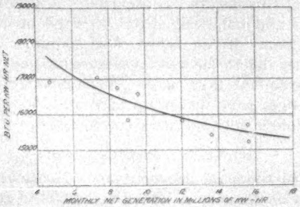

Fig. 4—B. t. u. Required for Various Monthly Outputs at Gould Street in 1927

From this outline, it is apparent that the plant has been subject to the usual minor changes and adjustments during the initial period of service. None of the troubles experienced was unsurmountable and all can be traced to the fact that most of the equipment affected was of the largest sizes that were obtainable, operating in many instances at rather high capacities. This introduced some problems that were entirely new, it being necessary for the manufacturers supplying equipment to do a certain amount of development after their apparatus was placed in service. While such a procedure is necessarily slow, it is felt that the manufacturers affected have made a very satisfactory record in solving their individual problems and in making necessary changes and connections.

The actual performance has approached fairly close to the anticipated, and it is apparent that, when the air heater performance is improved and the effect of the recent increase in steam temperature is realized, the anticipated performance will at least be met and possibly slightly bettered.

---

## Discussion

### THE GOULD STREET STATION

(Loizeaux, Leilich, Follmer, Dannettel, Penniman, and Quarles)

Baltimore, Md., April 18, 1928

**A. G. Christie:** There is a number of interesting features in connection with the Gould Street plant.

In the first place, this is the first large American station that has been built on the basis of one boiler to one turbine, and the performance has been quite satisfactory. It is not necessary to have many spare boilers as in some of the older stations. It is quite probable that in new station designs Gould Street's arrangement will be followed.

Another factor of interest is the steam turbine, in which capacity for size of frame is somewhat larger than has been common in the older stations. In other words, for a given size of turbine casing a larger output is obtained than would have been the case a few years ago. This, of course, gives a greater capacity in kilowatts for a given size of installation.

The use of condensers with rolled tubes at both ends is a decided advance. That construction was used in Europe quite a number of years ago but with very short tubes and not with the tube lengths used at Gould Street. As has been pointed out, it was necessary to run a number of tests to determine what would happen to longer tubes and how their expansion could be cared for in order to have the condensers operate satisfactorily.

The type of feed-water heater used is also unusual and apparently quite an advance over former types. The hairpin vertical type of heater takes up little room between the turbines themselves. It is easier to get at than some of the older types.

The air preheaters occupy a large volume. Larger and larger air preheaters will undoubtedly be used as stations grow in size, particularly since their advantages have become recognized.

In Fig. 3 of Mr. Loizeaux's paper, the turbine room is apparently outgrowing the boiler house. By the time the four machines on the present program are installed, the boiler house will be considerably smaller than the turbine room. That suggests the possibility that larger turbines will be required for later units. Some plants have adhered to the system of having equal sizes of turbines throughout the whole station, but when the possibility occurs of getting extra kilowatts in the same space, it is pretty hard not to add the larger units.

**L. W. W. Morrow:** I can say whole-heartedly that this is the best group of power-station papers I have ever listened to at the engineering meetings, in that the authors have very frankly told all their troubles and difficulties in connection with the installation and operation of a new power station. Sometimes there is a defensive league, I call it, among engineers whereby everything they do is perfect and they never admit that they could have made an error. It stands to reason that the engineers in this country today are largely responsible for the reductions in the costs of power. It stands to reason that in departing from past practises and in making the great economies that have been made in the last five or ten years in power production, there must occur some errors. There must occur some pioneering engineering developments, and to get full advantage of experiences with new things it is really worth while for the engineers to talk frankly about the new plants.

There are one or two questions that arise in my mind. The use of automatic equipment is to improve station economy and reduce station labor charges. My first question is in regard to the operation of automatic boiler-room control; does it work well? The second question is about labor. How many men per shift are used in this station; and what degree of skill is required for maintenance and for operation? Another question that comes to my mind is the use factor that you can expect out of a one boiler one turbine combination. Are the turbines and boilers equal in reliability from a service standpoint?

The station game today is developing rapidly. We are working water and materials to the full degree they can be worked. The power engineer has to think in terms of basic physics, metallurgy, and chemistry and must be ready to use other fluids and gases than water and air in order to meet the demand for reducing power costs.

**H. C. Sutton:** In building this plant the engineers, in selecting every piece of apparatus, have taken into account the first cost, interest on the investment, and operating cost, to give us the lowest annual cost.

I note that one feature of the design of the station is rather conservative. It certainly is conservative to select a boiler pressure of 450 lb. I might say that we are interested in the design of a station now to be located at Deepwater, where we will have 1380-lb. boiler pressure.

Another feature that is of interest and unique, is the very large boiler and the admirable design of one boiler per unit. I think that is worth considering in future station design.

Another conservative feature is the low voltage for the station auxiliaries, 440 volts. We, in our recent stations, have selected 2300 volts and 440, except in the smaller stations where we have used 550 volts. Of course, that is a matter of economy, but it has this particular thing to recommend it in design; with the use of 440 or 550 volts you largely limit or eliminate the use of oil circuit breakers which are necessary with 2300-volt auxiliaries. So there is a gain in using the air-type breaker for station auxiliaries that is a very material one, particularly where you have group buses located at various advantageous points throughout the station.

The preliminary design of the Deepwater Power Station to be located opposite Wilmington is interesting. In that station there will be three 12,000-kw., 1200-lb. units, one of these units being used for a power company which will take the steam and also take the electric load from this generator. The other two 1200-lb. units will be the high-pressure units for the two main generator units of the station, the low-pressure unit being 41,000 kw., making a total of 53,000 kw. per unit. The only boiler pressure will be the 1380-lb. boiler pressure, the steam merely going back to be re-heated before going to the low-pressure unit.

**R. L. Thomas:** An outstanding feature of the Gould Street Plant is the unusual amount of attention given in design to what has recently been called "dollar efficiency." Other plants have been built during about the same period with lower fuel rates, but in considering those rates there should always be taken into account the cost of the corresponding equipment.

One question occurs to me. The Gould Street loading is such that there has been considerable "banking" at regular intervals throughout long periods. Information regarding banking experience might be of interest, for example, as to how boiler pressure is allowed to decrease during long and short banks, what intermediate firing is done, etc.

**J. C. Stott:** There is one feature to which I wish to call attention,—that is, the physical layout of the plant itself and of the apparatus in the plant. The plant has been built on about as small a piece of property as is possible without sacrificing any of the operating problems. The outstanding feature in the development of this property was the fact that it was so close to our load centers. The conditions there were very unsatisfactory in so far as foundation was concerned. The foundations, caissons, and footings for the various structures required special considerations. We have made a very economical plant layout when considering the many difficulties.

**F. O. Schnure:** I want to ask the authors if they have found it necessary to use all of the 53 points on the induced-draft fan control. Another question is—what method is used in grounding the generators, through reactor or resistance?

**M. M. Price:** Reference has been made in the discussion to the conservative design of this station. From the point of view of 1928, the design is conservative, but the plant was designed and purchased in 1924 and 1925 and the boilers were among the first Babcock & Wilcox boilers, if not the first, to be built for a pressure of 450 lb. with riveted steam drum 60 in. in diameter and with tubes 24 ft. long, and the amount of steam which it was planned to generate in each unit was considerably in excess of the ratings usually considered. The rating demanded of the boilers was so in advance of the practise at the time the boilers were designed that it necessitated redesigning the steam baffles in the drums. This redesign was only carried out through the hearty cooperation of the operating engineers and has led to a distinct advance in securing dry steam at high ratings.

Boilers of higher pressures were considered when the plant was designed but the data on stations designed for such high pressures were not sufficient at that time to justify the selection of a higher pressure, especially when consideration was given to the load conditions under which the station was expected to operate, which conditions still exist.

**A. S. Loizeaux:** In answer to Mr. Schnure's question, I would say that our Gould St. neutral is solidly grounded. We have recently put a ¾-ohm reactor in the neutral of our 25-cycle system and in the course of time we may do the same thing in our 60-cycle system to reduce the destructive current in the event of short circuits.

Professor Christie was very modest in his discussion. He was called in consultation on a good many matters while we were designing the Gould St. Power House and due to his wide experience in the design of plants in this country and his knowledge of European power houses he was of real help in the design of the Gould St. Plant.

The designing was done in our own engineering department and drafting rooms. The company's construction forces carried out the work. Contractors were called in for a few of the larger elements of the work. One of the more interesting elements was the caisson foundations required. The Foundation Company of New York was employed to obtain the benefit of their experience and use of their supervisory talent. The caisson foundations under the power house are sunk to 50 ft. below mean low water. The caissons supporting the coaling tower were constructed on shore, like boats, and floated out into place, then sunk and lowered to minus 50 ft. with the open method. Air was then put on the caissons and they were sunk minus 70 ft. with the compressed-air method.

In connection with the water walls of the furnaces, it was unknown what would happen at very high capacities with reference to the production of smoke but we find that there is no excessive smoking at the higher capacities that we have carried. This fact is very fortunate and permits large capacities and overloads on boilers. Mr. Price of the B. & W. Co. and other agents of manufacturers gave us excellent cooperation in the design and construction and entered into the problems involved in a way that insured their proper solution.

**A. L. Penniman, Jr.:** All of the difficulties experienced in this plant were confined to apparatus that differed in one or more points from equipment for similar purposes that has been in general use. For instance, the relatively poor quality of steam delivered to the superheater was brought about by using drum sizes and baffle arrangements which were normally used in boilers having 20-ft. tubes, and increasing the length of the tubes some 25 per cent. This means that the steam-to-water ratio at the outlet end of the tubes is necessarily very much higher, the velocities are accordingly higher, and the problem of separation in the drum becomes increasingly more difficult. In addition to this the boilers are arranged with furnaces which will permit of their being operated at relatively higher rates of evaporation than has been the general practise.

One question that I had anticipated would be raised in the discussion of this paper, and which would seem to be an entirely logical one is: "Why, after 15 months of operation, do we still have some of these difficulties that have not been ironed out?" This is due in part, at least, to inertia. In the first place when we get into trouble it takes some time for the operating men to form an opinion, after which the chances are probably 5 to 1 that the designing engineers do not agree with them and additional time is spent in the attempt to find a common ground. It is quite probable that the manufacturer is not going to agree with the compromise which we have reached among ourselves, so that additional time is required to arrive at some preliminary decision which frequently does not lead to a correction of the trouble, due to the fact that while we may think we know the physics and mathematics of a lot of these problems, we usually find after we get the final solution that there were many unknown factors. However, we must remember that the plant is doing substantially what it was designed to do. The figures in the curve of the paper were made before the steam temperature was raised. The air heaters have failed to meet the anticipated performance given by the manufacturer simply because laboratory experiments indicated higher rates of heat transfer than we have been able to obtain in practise. At present there seem to be very definite indications that the heat lost by radiation from the steam generating units is greater than was anticipated. On the other hand the heat-absorption rate of the boilers is apparently somewhat better than we had anticipated so that the curve, which shows a variation of about 2½ per cent from the designers' anticipated results, can be accounted for as being due to poor performance of the air preheater and to low steam temperature.

Another question that I had anticipated is: "What conclusions have we been able to draw from the operation of this plant that might guide us in future additions or in the building of another plant?" In the main there are three general points; one is, if you are going to use pulverized coal prepared by a central system, do not try to start up in cold weather. The humidity is so much higher in cold weather that the tendency to gum the mills transport system, and ground-coal bins, is very much greater than in the summer, and is very likely to be further aggravated during the time necessary to get the coal-drying apparatus tuned up. We had numerous cases of the plugging of transport pumps and transport lines, the mudding up of the return air lines from the cyclones to the mills, and the mudding up of the mill cyclones. The switching valves in the coal transport lines stuck frequently. The furnace feeder screws mudded up and the coal arched over the throat of the feeders. At times it was hardly possible to deliver enough coal to the furnace to keep up steam pressure on the boiler. As soon as we were able to dry the coal properly all of these difficulties disappeared.

Secondly, a great deal depends on the proper method of drying coal. Our experience with grid driers was most unfortunate. As a matter of fact they simply refused to dry at all, and in addition so impeded the flow of coal to the mills that it was necessary to remove a large percentage of the grids in order to get coal through them at a sufficient rate. We have now been using the mill-drying scheme for some five or six months. We are feeding air heated to slightly less than 400 deg. fahr. into the mill with the return air, and venting a comparable amount of air from the system at the air-outlet side of the mill cyclone. There have been no troubles from this system. The reduction in temperature of the air is very rapid due to the evaporation of the moisture in the coal. Apparently the air temperature drops from 400 deg. fahr. to less than 165 deg. fahr. in the first 12 or 14 in. of travel of the air, while the temperature in the mill does not exceed that reached without air drying by more than 5 deg. The method used to control the amount of heat to be added is to vary the amount of hot air applied so as to maintain a fairly constant temperature of the coal-air mixture leaving the mill.

The third point is the question of steam temperature. I am rather convinced that there is no reason why in the next installation we should not go to 800 or 825 deg. fahr., for the steam temperature leaving the superheaters, or for that matter why this higher temperature should not be generally used. This is the greatest opportunity for gain in economy, and at a relatively small expenditure, that is presented to the designer at the present time. With the present inter-deck superheaters we frequently get rather high temperatures with no serious effect on the superheater, and no apparent effect on the turbine. We have radiant-heat superheaters installed in the bridge walls in some of our stoker-fired furnaces at Westport, which have been in service for nearly five years, operating with metal temperatures up to 1100 deg. fahr. They are in series with convection superheaters at the top of the first and second passes of the boilers, and maintain a very uniform steam temperature over quite a range of rating. The radiant-heat superheaters are not fitted with any type of flooding device and the boilers are banked frequently for protracted periods. If these superheaters will stand this sort of punishment, I can see no reason why we should not approach the same condition at Gould Street, and I anticipate raising the steam temperature as soon as we have some of the other operating problems cleaned up.

**F. W. Quarles:** Mr. Morrow asked how many men we require. I believe they average about fourteen per shift. The use factor of the boilers at the present time has been governed considerably by some of the changes that have taken place in the plant to rectify certain conditions. I think that at this time we cannot draw any satisfactory conclusions as to the use factor. Mr. Morrow also asked about the maintenance of the automatic control. So far the maintenance of the automatic control has been comparatively small on standard equipment. Where we have used new schemes we have got into difficulties, but in the case of the combustion control which is composed of standard pieces of equipment, it has had a very large job to do, much larger than in the usual plant. That is, on the induced-draft and forced-draft fan controls there are four drums that must be operated by this control, and there has been occasional trouble with interlocks which have caused breakage of some chains and other parts, but with the improvement of the interlocks, and the strengthening of certain parts, maintenance of this control should be cut down materially.

There was a question raised by Mr. Thomas about banking.

I don't believe we have any figures that we could furnish at this time regarding the amount of coal required in banking. We don't have any easy means of measuring it at the present time. However, it requires, about once every four hours, the use of burners to bring the pressure back to normal, having allowed the pressure on the plant to reduce about 100 lb., the plant being shut down completely.

Mr. Schnure asked about the necessity of using the 53 points on the control of the induced-draft fans. We feel, in the case of this plant, that it is necessary to have a large number of points on the control of the forced and induced-draft fans because of the large range in speed that is required. In other words, in order to keep large fluctuations from occurring in the $CO_2$ value it is necessary to make small changes of air flow. Now in this case the adjustment is made by means of speed of the fans and very little by means of dampers. The only damper control is on the induced-draft fan and that damper control is of very little effect in the range where the motors are running. Most of its effectiveness is confined to the period when the boiler is running on natural draft.

The grounding of the neutral of the main generators is solid; there is no series reactor or resistance used.

# The Conowingo Hydroelectric Development
## on the Susquehanna River

BY ALEX. WILSON 3RD[1]
Associate, A. I. E. E.

***Synopsis.***—*The Philadelphia Electric Company, through its subsidiaries, has just completed construction of the Conowingo dam and powerhouse to develop the fall of the Susquehanna River from the tail-race of the Pennsylvania Water and Power Company's dam at Holtwood, Penna., to a point within four mi. of tidewater. This project ranks as one of the largest hydroelectric developments in the United States and is exceeded in size by the Niagara Falls development only. The speed of its construction, requiring less than two years from the start of construction operations to regular operation of the first units, is an outstanding achievement.*

*In an average year, 1,250,000 kw-hr. will be delivered in Philadelphia at 220,000 volts, from the initial installation of seven 54,000-hp. water-wheel units, (ultimately to be increased to 11 such units), resulting in a saving of more than 750,000 tons of coal annually. These water-wheels and generators, together with the 27-ft. diameter butterfly valves installed as head gates, are the largest from the standpoint of physical dimensions yet constructed.*

*The concrete dam of gravity type, 4630 ft. long, develops a normal head of 89 ft., and has created a lake 14 mi. long. The spillway section, 2385 ft. long, has been designed to pass a maximum flood of 880,000 cu. ft. per sec. and is surmounted by movable crest gates for maintaining a constant head-water level.*

*Relocation of 16 mi. of railroad together with many State and County roads and bridges was required in the acquisition of lands for the reservoir.*

*Unusual features of the design and construction of the dam and power station together with a general description of the entire project, are included in this article.*

---

THE Conowingo Hydroelectric Development, with an initial installation of 378,000 hp. in seven main units ultimately to be increased to 594,000 hp. in eleven units, ranks as one of the largest hydroelectric projects in the United States, as shown by the following table giving installed capacity in other large plants.

| Plant | Owner | Installed hp. |
|---|---|---|
| Niagara Falls | Niagara Falls Power Company | 425,500 |
| Conowingo | The Susquehanna Power Company | 378,000* |
| Muscle Shoals | United States Government | 260,000* |
| Holtwood | Pennsylvania Water and Power Company | 158,000 |
| Keokuk | Mississippi River Power Company | 150,000 |

*Initial Installation.

In the average year, the initial Conowingo plant will deliver 1,250,000,000 kw-hr. to Philadelphia and interconnected districts, resulting in an annual saving in coal of more than 750,000 tons.

From the standpoint of speed of construction, Conowingo is an outstanding achievement in the history of projects of similar size. Construction work was started March 8th, 1926, under Federal License approved February 20th, 1926, and on March 1st, 1928, less than two years after starting construction, the first units were placed in regular operating service.

It is the purpose of this paper to outline the general features of the project and to describe particularly the design and construction of the dam and power house, and hydraulic equipment.

### THE SUSQUEHANNA RIVER

With the exception of the St. Lawrence, the Susquehanna River basin is the largest and most important on the Atlantic Coast. Its total area of 27,400 sq. mi. includes 47 per cent of the total area of the State of Pennsylvania, 13 per cent of the total area of the State of New York, and two per cent of the total area of the State of Maryland, and extends north almost to Utica, N. Y., and west beyond Altoona, Pa.

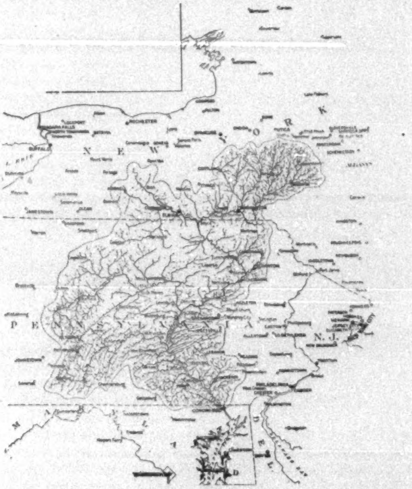

FIG. 1—MAP OF AREA DRAINED BY THE SUSQUEHANNA RIVER

The head waters of this river system are on the elevated plateau which separates the waters which flow south and east into the Atlantic streams from those flowing north and west into the Mississippi, St. Lawrence, and Great Lakes.

---

[1] Construction Engineer, Philadelphia Electric Co., Philadelphia, Pa.

*Presented at the Regional Meeting of the A. I. E. E., District No. 2, Baltimore, Md., April 17-20, 1928.*

From Northumberland, situated at the junction of its east and west branches, the river has a fairly uniform grade of two and one-half ft. per mi., except for local rapids between the Muncy Dam and Conewago Falls, near York Haven. Below, or in the lower 40 mi. of its course, the slope increases to an average of five ft. per mi. to tidewater, and the width of the river becomes contracted, narrowing into a gorge which, in places, is reduced to a width of two-tenths to one-half mi. In the last 27 mi. of its run, the river drops from an elevation of 225 ft., with an average slope of 5.6 ft. per mi., causing a swift current which has worn a low water channel of great depth in many places.

Along this lower section, the river has cut its way through a range of table land, and its bed is walled by steep, rocky bluffs on both sides, affording excellent foundation for water-power developments. A portion of the fall in this section has been developed by the Pennsylvania Water and Power Company's dam at Holtwood, Pennsylvania. The Conowingo Dam will utilize the head from the Holtwood tail-race to within four mi. of tidewater.

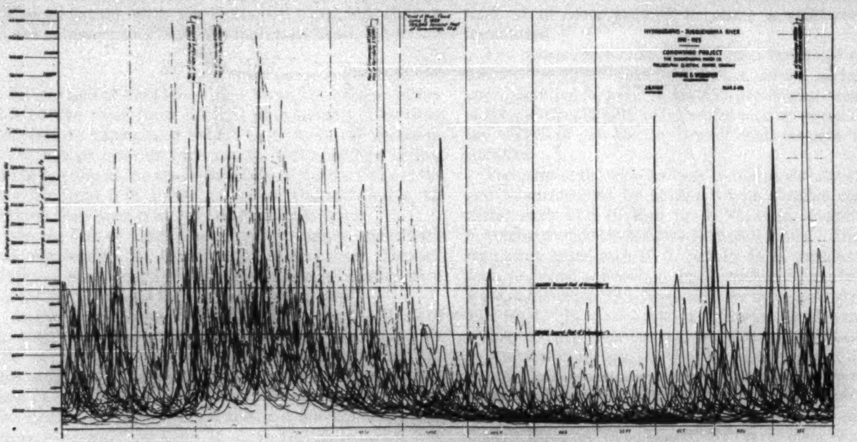

FIG. 2—HYDROGRAPHS—1891 TO 1925 INCLUSIVE

The annual precipitation over the area drained by this great river, according to records of the United States Weather Bureau, varies from 31.4 in. to 44.3 in., with a mean of 39.4 in.

The run-off, which eventually finds its way to the sea through the Susquehanna River, varies from 16.6 in. to 29.1 in. and averages 55 per cent of the rainfall. The run-off is at a minimum in August, September, and October, during which months it ranges from 5 per cent to 30 per cent of the rainfall and averages about 15 per cent. Reliable official records on the flow of the Susquehanna have been taken since 1891 at Harrisburg, which shows that, like all other Pennsylvania streams, its natural run-off varies widely both from day to day or week to week and from season to season.

High water frequently occurs in January from melted snow. Floods accompanied by ice gorges occur usually in March and result in a high water level, although with a lesser volume of flow than at times of clear water floods caused by heavy rainfalls, occurring over the whole or a portion of the water shed as late as June. In late summer or fall, periods of low water are frequently noted.

During the past century, there have been several great floods in this river, the most notable of which was that of June, 1889, which was coincident with, although not caused by, the Johnstown Flood, and which probably exceeded any flood that ever occurred in this stream. It is estimated that during this flood, the rate of flow reached a maximum of 730,000 cu. ft. per sec. A minimum discharge of 2200 cu. ft. per sec. was recorded at Harrisburg in 1909.

Due to the frequent recurrence of low-flow periods, which limit the amount of firm power available, large scale power development was not economically feasible until electric demand in nearby centers served from steam driven generating equipment, had become capable of absorbing the hydro power available during high-flow periods. This condition is met by the load of the Philadelphia Electric Company System and its interconnections with other utilities. Thus the Conowingo site, with a firm power value of but 30,000 kw., will initially deliver in Philadelphia 1,250,000,000 kw. hr. annually, resulting in an annual saving of more than

750,000 tons of coal and with the present shape of the daily load curve of the Philadelphia Electric Company System, the Conowingo plant can be relied on for a minimum peak capacity of 180,000 kw. which ultimately would otherwise have to be provided in steam plant capacity.

### CORPORATE ORGANIZATION

As the Philadelphia Electric Company will use practically the entire output of the Conowingo Development, it was necessary that it should control the operation of the plant. Its charter, however, does not permit it to operate or hold title to property in Maryland. These requirements were met by the organization of three subsidiary or otherwise controlled corporations, as follows:

The Susquehanna Power Company, incorporated in Maryland, to hold title to all the physical properties of the project located in that State, including the dam, power house and tail-race, and portions of the reservoir and transmission lines.

Philadelphia Electric Power Company, incorporated in Pennsylvania, to hold title to all physical property of the project located in Pennsylvania, this being principally lands for the reservoir and the greater portion of the transmission lines.

The Susquehanna Electric Company, which has leased for the term of the Federal License the properties of the Susquehanna Power Company in Maryland. This subsidiary under contract with the Philadelphia Electric Company operates the plant and sells the generated energy to the Philadelphia Electric Company. As set up, therefore, the Conowingo Hydroelectric Development has been made by and for the Philadelphia Electric Company, and is being operated as a part of that company's system.

### RELOCATION OF HIGHWAYS AND RAILROAD REQUIRED

The Conowingo Dam and Power House are located in Cecil and Harford Counties, Maryland, about six miles from the Mason and Dixon Line and four and one-half miles upstream from the town of Port Deposit. The reservoir above the dam has an area of 14 sq. mi. and extends above the dam a distance of 14.6 mi., of which 9.3 mi. are in the State of Pennsylvania. Relocation of 16 mi. of the Columbia and Port Deposit Branch of the Philadelphia, Baltimore, and Washington Railroad Company operating on the left bank together with numerous County and Township roads and one State road, including a steel-bridge crossing the river at Conowingo, Maryland, two mi. above the dam, were made necessary by the impounding of the waters in the reservoir.

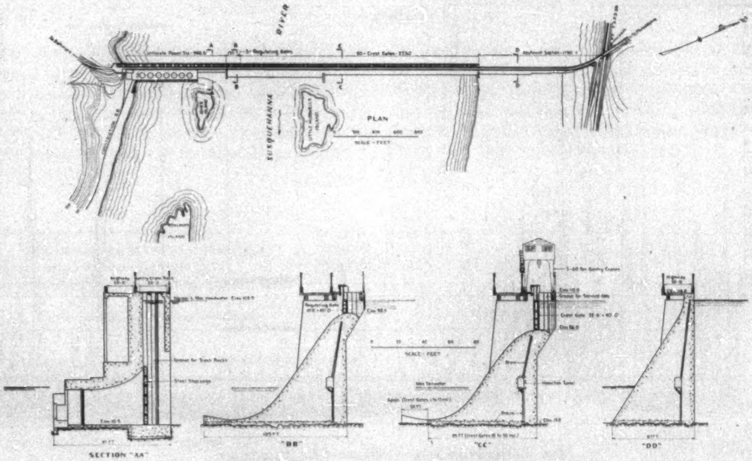

FIG. 3—GENERAL PLAN AND SECTIONS—CONOWINGO DAM

The total of these items involved a considerable amount of work. A new highway bridge with 20 ft. wide roadway, supported on the structure of the dam and power house has been provided together with 4.37 mi. of 18 ft. wide concrete highway connecting the new bridge with the existing State road on either side of the river. The relocation of the railroad on the left bank made necessary the construction of a double track road-bed from Port Deposit, Maryland, to Fishing Creek, Pennsylvania, and involved 1,460,000 cu. yd. of excavation (including borrow) 900 ft. of tunnel, 42,000 cu. yd. of concrete masonry in bridges and culverts and the laying of 20 mi. of single track.

### Maximum Pool Elevation

By agreement with the Pennsylvania Water and Power Company whose dam is located at Holtwood, Penna., upstream from the Conowingo Dam, a normal and maximum pool elevation, 108.5 ft. above sea level, has been adopted. At this elevation, the impounded waters of Conowingo Dam will be backed up over a portion of the Holtwood Plant's tail-race, which has not yet been excavated but which, if excavated, would result in increased head and power at the Holtwood plant. It was mutually agreed that this additional head could be developed more economically at Conowingo Dam, and arrangements were made, therefore, that the Conowingo pool should be maintained at the above elevation, with the Holtwood Company sharing in the gain accruing from the increased head.

### Site of Dam

At the site of the Conowingo Dam, the hills on either side of the river form natural abutments. The river bed and its banks, to a height well above the reservoir level, are of igneous formation. Core borings, drilled along the line of the up-stream face of the dam to depths varying from 5 ft. to 100 ft. below the rock ledge, all showed firm hard rock for their entire length.

On the left or Cecil County shore, ample space with rail connection to the Columbia and Port Deposit Railroad was available for the erection of construction camp and plant and for storage of materials.

As the main channel of the river ran along the Harford County shore, the power house has been located at this end of the dam. Space for construction plant at this side was somewhat limited by the rather abrupt rise of the river bank. To provide transportation facilities to the power house site, a single track railroad connecting with the Penn. R. R. in Havre de Grace was constructed on the tow-path of the old Tidewater Canal which formerly operated on this bank, but which has been abandoned since the latter part of the nineteenth century. A freight classification and material storage yard was established on Giles Island, located on the route of the construction railroad about three mi. below the dam.

### Design of Dam and Headworks

The dam is of solid concrete masonry construction, designed as a gravity section. Its total length, 4648 ft., includes the power house headworks, 950-ft. long and 2385 ft. of ogee type gate-controlled spillway section. To collect seepage water under the dam, and prevent excessive uplift, a longitudinal drain was installed on the foundation ten ft. six in. downstream from the face of the dam. Cross drains spaced 45 ft. on centers connect this drain to tail-water at the toe of the dam. Riser drains at all vertical construction joints connect the bottom drains to the inspection tunnel. To reduce seepage through the vertical construction joints, copper sealing strips were installed near the upstream face of the dam. Grout holes located two ft. inside the upstream face of the dam were drilled in the foundation to a depth of 20 ft., at 10-ft. intervals and grouted under 25 lb. pressure to form a cut-off wall against seepage through the foundations.

The dam and power house are founded on rock at an average elevation of about 12 ft. above sea level for the dam and 7 ft. for the power house. Due to folding and metamorphic intrusions, the rock surface presented, after removing all overburden and rock that could be barred loose and cleaning out all seams, was very rough and irregular and thus provided excellent bonding for the structures. Soft seamy rock was encountered in but two sections requiring more than removal of loose material to secure a satisfactory foundation.

The overhanging crest is an unusual feature of the spillway section. This permitted a curved surface, approximating the lower nappe of an overflowing stream of the depth of 22½ ft. to be formed without increasing the width of the section beyond that required for stability.

The crest of the main spillway is fixed at elevation 86 and is surmounted by 50 Stony type movable crest gates, each 22.5 ft. high by 41 ft. wide, operating in guides provided in concrete piers on the dam. Three regulating gates, each 10 ft. high by 41 ft. wide, have been provided adjacent to the power house on a fixed crest at elevation 98.5, for use in finer regulation of the pool level. In the design of the spillway, an allowance of 4000 lb. per linear foot was assumed for ice pressure at the water surface. A compressed air system, discharging air below the water surface upstream from the gates, has been provided to prevent formation of heavy ice against the gates. The above pressure was considered, therefore, to be concentrated at the piers. Electric heaters have also been provided to keep the gate guides free from ice. The gate piers, spaced 45 ft. on centers, continue up above the pool level, and support a runway at elevation 115, extending along the spillway section and power house headworks from which three electrically operated gantry traveling cranes operate the crest and regulating gates as well as the sectional head gates and trash racks on the power house. The gate piers also support the highway bridge, which has replaced the old Conowingo bridge, inundated in the reservoir.

The spillway section for the three regulating gates and 17 crest gates has been provided with a 20 ft. wide apron curving up from the toe of the dam to an angle of 12½ deg. with the horizontal in order to prevent erosion at the toe of the dam. Tests conducted at Worcester on a model of the spillway and apron indicated that the maximum erosion would take place about 150 ft. beyond the toe and might reach a depth of 25 or 30 ft.

below the river bed. These tests also indicated that practically no erosion would occur directly at the end of the apron.

The power house headworks section was designed as a gravity section to be stable, independent of the power house structure. The heavy bottom slab forming the floor of the intakes has been keyed into the foundations and the walls and roof of the intakes tied to this with heavy reinforcing to resist the uplift pressure on the intake roof. At the upstream face of the head works section, a reinforced concrete curtain wall extends to a depth of 40 ft. below the surface of the reservoir for the purpose of preventing ice and trash from entering the intakes below.

## POWER HOUSE STRUCTURE

The substructure of the power house, designed to meet the requirements of the water ways required by the hydraulic units and to support the superimposed loads of the water-wheels and power house superstructure, was constructed of reinforced concrete. A maximum depth of foundation excavations to elevation minus 20.5 ft. was required at the hydraucone draft tubes of the wheels. Where spreading type, draft tubes were used on three of the units, excavation was carried to elevation 16.5 ft. below sea level. Weep-holes were provided in the floors of the draft tubes to relieve excessive uplift pressures. At the downstream face of the substructure, the supporting piers have been extended to provide guides for draft tube stop logs.

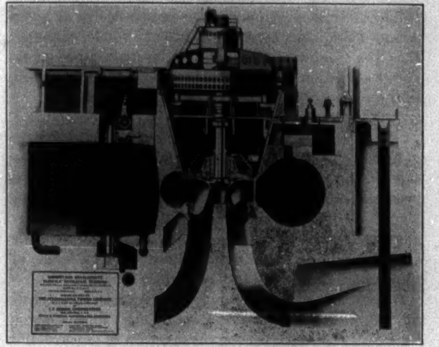

Fig. 5—Section Through Water Wheel Unit

Upstream from the units and below the level of the scroll cases, is an inspection tunnel from which access is afforded to each draft tube and to the butterfly valve thrust bearings and the valve in the unwatering system. Seepage through construction joints in the

Fig. 6—Plan of the Conowingo Station

substructure and head works is collected in a trench running in the inspection tunnel and drained to a sump at the west end of the power station, where two small pumps are provided. Below this tunnel is a 42-in. cast iron unwatering header draining to a drainage pump of large capacity located at the shore end of the station served by two 15,000-gal. per min. pumps. Each draft tube, scroll case, and intake upstream from the butterfly valve is connected to this unwatering header through suitable valve control piping so that this central pumping installation can be used to unwater any one unit if desired. The main power station superstructure of the initial installation includes the generator room, which is about 70 ft. wide by 75 ft. high by 650 ft. long. The electrical bay between the generator room and headworks is a two story building containing the 13,800-volt bus and switch compartments. Compartments for step-up transformers are located on the roof of the electrical bay, together with the main control room and the station service control room from which windows afford a direct view of the generator room. The 220-kv. switching station is located on the roof of the generator room. The frame of the power house superstructure is designed of reinforced concrete on a structural steel frame with reinforced concrete roof carried on steel trusses. All loads imposed by the switching station on the roof are carried down to the substructure through the steel columns heavily reinforced with concrete. The loads of the two 150-ton cranes are carried on separate steel columns which are tied in with the building columns for the lateral support only. A dismantling area designed for uniform load at 2000 lb. per sq. ft. has been provided at the shore end of the power station for the purpose of assembling such large parts as the generator rotors and water-wheel runners. A standard gage railroad enters the building at this point and also affords ready means of delivering material to the machine shop located beyond the generator room. An office bay has been constructed between the power house and shore and is equipped with an elevator operating between elevation 35 and the reception room, at the elevation of the highway bridge.

## Hydraulic Equipment

Initial installation provides for seven 54,000-hp. Francis runner, vertical-shaft water-wheels, operating under normal head of 89 ft. and at 81.8 rev. per min. each direct connected to a 40,000-kv-a., three-phase, 60-cycle, 13,800-volt generator. These water-wheels, generators, and valves are the largest in physical dimensions constructed to date.

There are also two 1900-hp. station service units.

The shape of the intake was determined largely by the use of butterfly valves as head gates for the water-wheels, permitting the intakes to be designed with a wide entrance near the bottom of the river and low entrance velocity, which is accelerated uniformly to a maximum in the scroll case. The intake of each main unit is divided into two sections by a vertical reinforced concrete wall which extends to within 22½ ft. of the center line of the butterfly valve. Guides for steel head gates and sectional trash racks have been provided at the entrance, together with guides for a mechanical trash rake which operates on rails on the headworks. Head gates and trash racks are operated by the same gantry cranes described for the crest gates.

Seven water-wheels are connected to generators of different manufacture. All water-wheel runners have been designed with the same clearance dimensions and the same number of speed-ring vanes and guide vanes. The waterways have the same general dimensions and the valve control mechanism and various auxiliaries are alike. As the runners of the different manufactures are interchangeable, only one spare runner is required. Four water-wheels have draft tubes of the hydraucone type. Spreading draft tubes have been constructed for the other three water-wheels. The governors are of the actuator type with flyballs driven through gearing from the main shaft and are operated by oil pressure cylinders. There is one oil pressure system for each pair of units. An oil storage and purification system has been provided for all of the governors and bearing oil of all units, including station service units. With each main water-wheel unit, a 27-ft. diameter vertical shaft, butterfly valve, complete with operating equipment, oil pressure system, and accessories, has been installed at the water passages to the runners. These valves have a cast steel housing and a wicket of cast steel, a forged steel shaft and a plate steel penstock liner, extended 12 ft. upstream in the intake passage. These valves are operated by oil pressure from a central oil pressure system. All butterfly valves and the plate steel scroll cases to which they are attached have been furnished by the same manufacturers as the

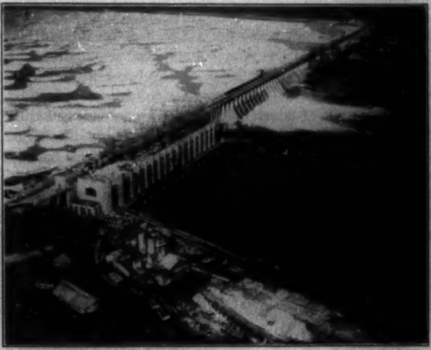

Fig. 7—Aerial View of Completed Dam and Power House, Taken February 1927

respective water-wheels units on which they have been installed. The weight of the rotating elements, together with hydraulic thrust, is carried by the thrust bearings on top of the generators. These bearings are supported by bracket arms extending radially from the structural steel pit liner, which also supports the stator of the generator. Both spring-type thrust bearings and Kingsbury thrust bearings have been used.

### RIVER DIVERSION AND CONSTRUCTION METHODS

At the beginning of the work, a progress schedule was carefully worked out to determine the progress necessary to be made by the various operations of the work to coordinate these operations with the scheme of river diversion. This schedule contemplated operation of the first two units on June 1st, 1928. Construction progress, however, was considerably better than scheduled with the result that two units started commercial operation on March 1st, and a third unit, a few days later.

In the low-water season of 1926, a cofferdam of the puddle-chamber type was constructed enclosing the power house and west branch of the tail-race, an area of about 14 acres. The top of this cofferdam was built to elevation 42, at which elevation it was estimated that it would not be topped by flood of any volume less than 350,000 cu. ft. per sec. so that work on the heavy excavation of the power house foundations and draft tubes could reasonably be expected to proceed without interruption by floods in the Spring of 1927. Simultaneously with the construction of the power house cofferdam, another cofferdam of the spaced crib type was constructed from the Cecil County shore, extending to within approximately 700 ft. of the power house cofferdam. About the middle of November, a flood of 350,000 sec. ft., the greatest November flood that has been recorded for the Susquehanna River occurred. The head water elevation rose to within a few inches of the top of the sand bags which had been placed on the power house cofferdam and, of course, topped the spaced crib cofferdam on the other side of the river. As the foundations for the dam had been completed in this area with alternate spillway sections each including two bridge piers poured to a height above the river level, it was not necessary to unwater this cofferdam again after the flood has subsided.

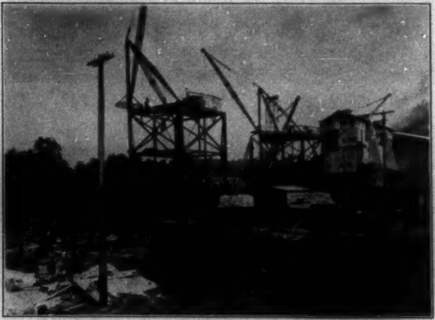

FIG. 8—CONSTRUCTION PLANT—EAST SIDE OF RIVER

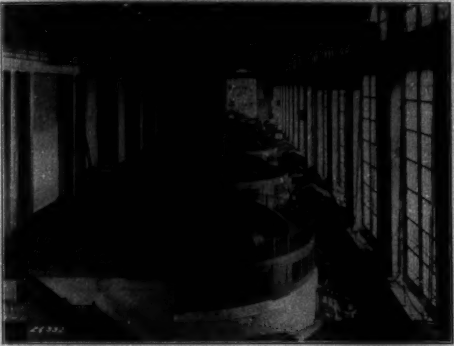

FIG. 9—GENERATOR ROOM—CONOWINGO STATION

During the winter and early spring of 1927, the pouring of the pier sections was completed up to and including the highway bridge, leaving intermediate sections 38 ft. wide at the level of the foundation (elevation 22) to provide for the diversion of the river during the summer of 1927. Likewise the power station headworks was completed during this period up to an elevation well above flood levels.

As soon as the spring floods of 1927 had sufficiently subsided, the cofferdam was extended from the last completed spillway section to the power house headworks, and by September, the foundations of the dam had been completed in this last cofferdam and the alternate sections poured above the elevation of the top of the cofferdam. With the removal of this cofferdam, twenty 38 ft. wide notches in the spillway, together with eight 10 ft. high by 18 ft. wide sluices through the spillway, were taking care of the river flow.

Final closure of the notches was commenced early in October, 1927. The easterly ten notches were first brought up to elevation 30, and the west ten to elevation 35. These two groups, with a 5-ft. difference in bottom grades, were then raised alternately in 10-ft. lifts, thus providing 5-ft. flow through ten openings in addition to the flow through the eight sluices. In the actual closing of the water-way at each 38-ft. opening, a steel and timber flap gate hinged at the top from the adjoining spillway sections was used. The gantry cranes provided for the crest gates were used to handle these flap gates. With the raising of the notches and corresponding rise of the headwater level, the discharge capacity of the eight sluices increased so that finally, when the notches had been raised to about elevation 50, the discharge from the sluices was equal to the river flow and the closing of the notches was completed without the use of the flap gates.

After the concrete in the notches had been completed to crest elevation, final closure of the eight sluices was made by lowering specially designed, reinforced concrete gates, weighing 75 tons each, and then filling the sluiceway opening with concrete.

Closure of the notches was hampered through November and December, 1927, by high water. Favorable flow conditions occurred in January, however, permitting completion to crest elevation on January 16 and on January 17, 1928, the sluiceway gates were dropped, making the final closure of the dam.

For the construction of the dam, a steel work trestle with deck at elevation 60 was built on the toe of the dam. Three self-propelled, electrically-operated gantry travelers, each equipped with a 15-ton steel derrick and concrete elevator, were used, the travelers operating on rails at the sides of the trestle deck and being designed to allow clearance for cars operating on the three standard-gage tracks, also provided on the trestle deck. The concrete mixing plant for the dam consisted of four mixers of 2-cu. yd. capacity each, and was so designed that the mixers discharged directly into hoppers mounted on cars on the work trestle. Gasoline locomotives were used to transport the concrete from the mixing plant.

In the construction of the power house and headworks, a central concrete mixing plant consisting of two mixers of two cu. yd. capacity each, was used. Placing of concrete was accomplished with 16-in. chutes from wood towers 250 ft. high. Guy derricks were used in handling forms and other materials. Erection of structural steel was accomplished by use of a traveling derrick mounted on the headworks. This traveler was also used to erect the steel arbor structure of the 220-kv. switching station on the roof of the generator room.

The following quantities involved in the construction of the dam and power house will be of interest:

| | |
|---|---|
| Cofferdam Cribs | 4,250,000 cu. ft. |
| Rock excavation, including tail-race | 348,000 cu. yd. |
| Forms | 3,850,000 sq. ft. |
| Concrete | 660,000 cu. yd. |
| Structural steel | 9,500 tons |
| Reinforcing steel | 6,400 tons |
| Hydraulic machinery | 6,500 tons |

A maximum working force of 5300 men was employed on the project.

The design and construction of the dam and power station, including installation of hydraulic machinery and 13,800-volt electrical equipment, the relocation of the tracks of the Columbia and Port Deposit Railroad, and the design and construction of the 220-kv. switching station on roof of generator room and the transmission lines, were awarded to outside contractors. Acquisition of all lands required by the project and all negotiations with Federal, State, and County Commissions were conducted by the Power Companies direct. All matters of design and construction were also under the general supervision of the Power Companies.

## Discussion

For discussion of this paper see page 906.

# Electrical Features of the Conowingo Generating Station and the Receiving Substations at Philadelphia

BY R. A. HENTZ[1]

Member, A. I. E. E.

***Synopsis.**—The paper outlines the principal electrical features of the Conowingo development. This includes a description of the main units and their connections, and an outline of the station auxiliary supply and the 220,000-volt substation which it was necessary to build on the roof of the power plant.*

*A description is included of the 220,000-volt substation at Plymouth Meeting, the Philadelphia terminus of the Conowingo lines, as well as the lines of the Pennsylvania-New Jersey Interconnection. At this substation are located the 30,000-kv-a. synchronous condensers installed for stability purposes, as well as a 66-kv. installation. Three winding 220/69/13.3-kv. self-cooled transformer banks of 130,000-kv-a. rating, arranged for tap changing under load, are installed here.*

*A description is also included of the Westmoreland Substation where the 66-kv. lines from Plymouth Meeting tie in with the 66-kv. "backbone" of the Philadelphia Electric System. At this substation, 30,000-kv-a. synchronous condensers for power-factor correction are located, as is also an extensive 13,200-volt installation for controlling transmission lines to various distribution substations.*

* * * * *

THREE stations or substations are involved in delivering the electrical energy from the Conowingo development into Philadelphia:

a. The Conowingo Hydroelectric Generating Station.

b. The 220/66-kv. step-down substation at Plymouth Meeting just outside Philadelphia.

c. The combined 66-kv. switching station and 66/13.2-kv. substation in Philadelphia (the Westmoreland Substation) where tie in with the existing system of the Philadelphia Electric Company is effected.

These, together with the steam generating stations and high-voltage substations of the Philadelphia Electric System are shown in Fig. 1.

## CONOWINGO GENERATING STATION

The ultimate development provides for eleven 40,000-kv-a. generators and three 220-kv. transmission lines, of which seven generators and two lines are being installed initially.

*13.8-Kv. and 220-Kv. Layout.* Fig. 2 is the main one-line diagram, the initial installation shown solid, the future dotted.

The 40,000-kv-a. main units generate energy at 13,800 volts and step up to 220,000 volts through 80,000-kv-a. transformers. It is planned to operate the plant as a whole in parallel on the 220-kv. bus, but to reduce the cost of transformers and 220-kv. switching equipment, two generators are tied together and to a transformer bank, thus forming an 80,000-kv-a. group. Thus ultimately, if such operation is satisfactory, there will be six such groups paralleled only on the 220-kv. side, except that the last one (generator No. 11 and transformer No. 6) will be necessarily of but 40,000-kv-a. capacity.

Should it at some future time be deemed desirable for any reason to operate in parallel on the 13.8-kv. side, then by means of additional construction the various buses of this voltage may be tied together, some through reactors, to form either a four-section ring bus or a three-section straight bus. The reactors may be cut out by means of a disconnecting switch (operated only when no current is flowing through the reactor). Initially the No. 3-No. 4 and the No. 5-No. 6 sections are tied together by an oil circuit breaker, thus providing greater flexibility of operation between these four generators. It will be noted that generators Nos. 3, 6, and 9 and transformer banks Nos. 2, 3, and 5 may be double-bussed in the future should the 13.8-kv. ring be formed. This is to permit testing a 220-kv. line from a generator (about one-half the capacity of which is required for such test) with the least interference to the maximum output over the remaining line or lines.

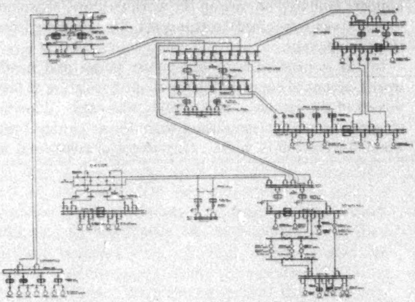

FIG. 1—MAJOR CONNECTIONS OF THE PHILADELPHIA ELECTRIC CO. SYSTEM

There will be two feeders, each connected to separate sections of the 13,800-volt bus to supply a transformer bank used for station service, and provision is made for two other feeders for the future supply to communities in the vicinity.

Two plans for the 220-kv. structure were considered;

---

[1] Engineer, Station Electrical Division, Philadelphia Electric Co., Philadelphia, Pa.

*Presented at the Regional Meeting of the A. I. E. E., District No. 2, Baltimore, Md., April 17-20, 1928.*

one a complete double bus layout which due to the characteristics of the site would have to have been located on the west shore some distance from the power house with consequent high cost and operating inconveniences due to distance from the operating room; the other the most flexibly operated bus that could be located on the roof of the power house, which location would be considerably cheaper and more conveniently operated than the first. This latter was decided upon, as it was possible to develop quite a flexible layout within the space limitations and to incorporate two features, inherent in a double bus layout, that were felt to be essential. These were reserve oil circuit breakers for the lines, and immunity from protracted shut-down due to failure of a part of the bus. On account of their more frequent tripping and the speed with which lines can be restored to service, as well as the greater capacity involved, reserve breakers for the lines were considered essential, whereas one oil circuit breaker was felt to be sufficient for a transformer bank.

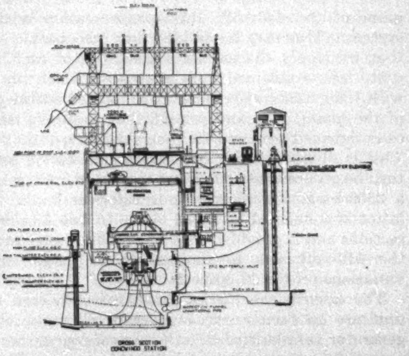
Fig. 3—General View of the 220,000-Volt Installation on the Roof

To the left, 2,500,000-kv-a. oil circuit breakers; to the right, 220-kv. lightning arresters.

The reserve line oil circuit breakers are located at the ends of the 220-kv. structure and connect the main tie bus with the ring bus. They are provided



CROSS SECTION CONOWINGO STATION

Fig. 4—Conowingo Power Station Cross-Section

with the same relay equipment as the regular line breakers, and by opening the latter and closing the ring-bus-line air-break switch, (which is motor-operated and interlocked in the same manner as the bus sectionalizing switches), the reserve breaker is electrically substituted for the regular one. Fig. 3 is a general view of the 220-kv. oil circuit breakers.

Quick isolation of a defective section is provided for by several motor-operated bus sectionalizing air-break switches. These are arranged so that they cannot open or close under load by an interlock consisting of a plug, the insertion of which in a certain receptacle will close the operating circuit of the air-break switch motor, provided the several associated air- or oil-break switches are in such a position (open or closed) that no current will be interrupted by the particular air-break switch to be operated.

The above outlines the essential features of the electrical layout. A cross-section is shown in Fig. 4.

*Station Auxiliary System.* Fig. 5 is a one-line diagram of the 440-volt, three-phase station auxiliary system. This may be divided into two parts: first, that to supply the essential auxiliaries of each main unit (this is obtained from alternators which together with their exciters are directly connected on the shaft of the main unit); and second, that to supply the less essential auxiliaries and the general lighting of the plant. This is obtained from two 1600-kv-a. station service turbine generators (with direct-connected exciters), and a 2500-kv-a. station service transformer bank. This latter is connected as noted above to two 13,800-volt sections and is provided with an induction regulator on the 440-volt side to compensate for large voltage variations on the 13,800-volt side.

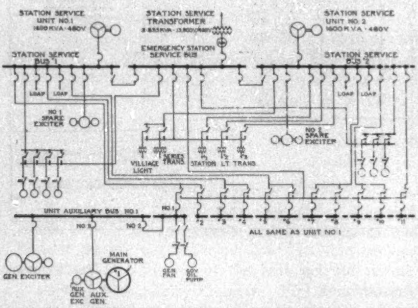


FIG. 5—440-VOLT STATION SERVICE AT CONOWINGO

The essential auxiliaries associated with each main unit are an exciter set, a governor oil pump, and a generator ventilating fan. Of these of course the most essential is the exciter and for this reason the unit auxiliary bus is divided into two parts tied together through a circuit breaker, so that the generator fan and governor oil pump may be disconnected, allowing the shaft-end auxiliary generator to continue driving the motor-generator set. The governor oil pumps for each pair of units are each capable of supplying the governors of both main units and both are running all the time. The generator fan is not needed when the air is being discharged into the turbine hall.

Emergency supply to all of these essential auxiliaries is obtained by feeders from the station service buses, one feeder being extended for each pair of generators. In addition there is another emergency feed common for all generators.

The general station service supply is from a single bus sectionalized into three sections which are tied together by air circuit breakers. To each section a station service turbine generator or transformer bank is connected so that the bus may be operated in one, two, or three parts as desired.

A spare motor-driven exciter for the main generators is connected to one of these sections and a second spare exciter may be added to another in the future. The miscellaneous motors throughout the plant are supplied in practically every case by two feeders, extended from different sections. It will be noted from the diagram that the main feeders are connected to the bus section supplied by the turbine generator units and the emergency feeders to that supplied by the transformer bank.

The lighting is obtained from three 200-kv-a., single-phase, 440/110-220-volt transformers. The lighting is thus divided into three independent parts, though each part may be supplied from either of two transformers by means of double-throw knife switches. In each of these three lighting groups is a number of circuits which will be thrown over automatically to one of the two control storage batteries in the event of failure of the regular a-c. supply. Two 20-kv-a. series lighting transformers are installed for lighting the highway over the dam. A bank of transformers stepping up to 2300 volts, three-phase, is used to supply service to the operating village nearby. Air circuit breakers are used throughout on the 440-volt auxiliary system.

*Excitation System.* As noted above, each of the main generators is excited from individual motor-generator exciter sets. These consist of a 375-hp. induction motor, a 240-kw., 250-volt main exciter, and a 10-kw., 250-volt pilot exciter operating at 1200 rev. per min. Consideration was given to having these exciters mounted on the same shaft with the main unit, but due to their capacity and the slow speed (81.8 rev. per min.) a very expensive exciter of quite large dimensions and of slow response would have resulted if indeed they could have been satisfactorily built. As high-speed excitation was essential for stability of operation, it was necessary to use motor-generator exciters.

This high-speed excitation has been described in the technical press.[2] The regulator is a combination of rheostatic and vibrating contact types, the general principle being that for sudden changes of load the contacts raise or lower the voltage very quickly and the face plate rotates to a new position after which the contacts cease vibrating. This combines the advantages of the two types, obtaining the quick response of the one and the reduced contact maintenance of the other.

---

[2] "Quick Response Excitation for Alternating-Current Synchronous Machines," C. A. Powel, *Electric Journal*, April 1927, p. 157.

Circuit breakers are installed so that excitation for each unit may be obtained either from the regular motor-generator exciter, or either of the two spare exciters. Emergency excitation for the auxiliary generators and the station service generators may be obtained from the spare exciters in the same manner.

*Main Generators.* The main generators are of unusual size, rated 40,000 kv-a., 36,000 kw., 90 per cent power factor, 13,800 volts, three-phase, 60 cycles. Though there are others of larger kw. capacity, yet on account of their slow speed, these are physically the largest ever built. They are provided with 88-poles and operate at 81.8 rev. per min. Mounted on the same shaft and above the thrust bearing is a 715-kv-a., 500-kw., 70 per cent power factor, 440-volt, three-phase, 60-cycle generator and its 41-kw. 250-volt exciter. Four of the units are provided with spring type thrust bearings and the other three, with Kingsbury thrust bearings. The designs of the two manufacturers who built the generators have been so worked out that the units have the same general dimensions, which adds greatly to the appearance of the generator room. The neutrals of both the main and auxiliary generators are brought out for differential relay protection and in the case of the main generators are then grounded through a 4-ohm resistor which is common to all of the units, even though groups of these generators are separated from one another on the 13,800 volt side. The neutrals of the auxiliary generators are ungrounded. Fifteen temperature resistors are provided in the main machines and operate recording temperature indicators. The generators are roughly 38-ft. in diameter, 32-ft. high, and weigh, together with the thrust bearing, auxiliary unit and its exciter, well over 500 tons on the average. See Fig. 6. The weight on the thrust bearing including water thrust is 1,200,000 lb.

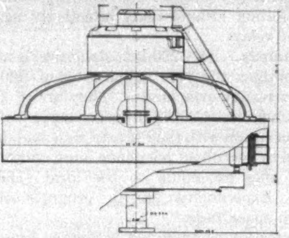

FIG. 6—40,000 KV-A. GENERATOR

*Main Transformer Banks.* Each main transformer bank is of 80,000-kv-a. capacity, consisting of three 26,667-kv-a. units, Y-connected on the 220-kv. side, with solidly and permanently grounded neutrals, and delta on the 13.8-kv. side. Four of these banks are being installed initially together with a spare single-phase unit, making thirteen transformers in all. They are provided with one seven and one-half per cent tap in the high-tension winding and are insulated for 187 kv.

The units are water-cooled and normally receive their water supply directly from the lake formed by the dam, the water flowing through the cooling coils by gravity. When reduced pond level makes it necessary, motor driven pumps supply the cooling water.

The transformer may be run on its own wheels on to a transfer car which carries it to the west end of the plant, where a crane lowers it to the same level as the generator room into which it is run over the yard tracks.

*Oil Circuit Breakers.* The oil circuit breakers for 220,000-volt service are rated 187-kv., 1000-ampere, 2,500,000 kv-a. rupturing capacity. Potential networks are attached to the condenser bushings which will supply potential for synchronizing and the operation of impedance relays and instruments. These breakers in their permanent position rest on two I-beams. Their removal is accomplished in the following manner: Four jacks raise a single pole of the breaker a sufficient distance to allow a small car to be slipped under it; it is then lowered until it rests on this car in which position it just clears the I-beams. This small car with the breaker is then moved on to a larger car which is then moved to the west end of the station, where the smaller car carries the breaker under a crane which lifts it down into a bay similar to those in which the main transformers are located. From here it is taken into the plant in the same manner as the transformers.

The 13.8-kv. breakers are rated 15 kv., but are insulated for 25 kv. as are also all the insulators and current transformers. The generators and light and power breakers are of 2000 ampere capacity, the bus tie of 4000 ampere capacity. They are motor-operated, and have a rupturing capacity of 1,500,000 kv-a. The section of the station in which they are located is divided into a number of smokeproof compartments so that fire and the resulting soot will be confined to a comparatively small area.

*Relays.* The main generators have percentage differential relays *P Q Y*-28, which take care of phase-to-ground and phase-to-phase faults. No provision is made for short circuits between two sections of the same winding or between turns of each section. Overvoltage *C V* and mechanical overspeed relays with their contacts in parallel protect against excessive frequency and voltage that may occur upon sudden loss of load.

The unit auxiliary and station service generators have single winding differential relays *P Q* and in addition the station service ones have overload *C O A* protection.

The main transformers are equipped with two-winding differential relays *P Q*-21 and low energy ground relays *C O* on the low-voltage side. In addition overload relays *C O A* provide protection against a 220-kv. bus failure between phases and act as back-up relays for the phase-to-phase relays on the 220-kv. lines.

The station service transformer bank is protected by differential *P Q*-21 and overload *C O A* relays. Since the two 13.8-kv. sections which supply this bank would be left together if both the two breakers that control it were left closed at the same time, a long time auxiliary relay operates an alarm, thus warning the operator of this condition.

The 13.8-kv. bus sections are protected by differential *P Q Y*-28 and low energy ground *C O* relays. The two bus sections which may be tied together require a slightly amplified scheme over that required for the two that are entirely isolated.

The 220-kv. line breakers and the 220-kv. bus tie breaker (which as pointed out above may be substituted electrically for them) are each provided with:

a. Three low setting directional impedance *C Z* relays to provide phase-to-phase protection. Due to the fact that the maximum line current is so great and the range of connected generating capacity so large, it is possible to have phase faults with minimum generating capacity involving less than half maximum full load current. In order to properly clear under minimum generating capacity conditions and to prevent the maximum full load current from tripping the lines

b. Three instantaneous undervoltage *S V* relays.

c. Three instantaneous over-current *S C* relays are provided whose contacts are in parallel. The operation of either of these in turn operates

d. One auxiliary *M C* relay whose contacts normally short circuit the current coils of the impedance relays *a*. In case of fault occurring with minimum generating capacity, the voltage relay *b* operates allowing the impedance relay *a* to function; in case of fault occurring with maximum generating capacity the current relay *c* operates allowing the impedance relay *a* to function. Thus, heavy load currents will not cause relay operation unless of such high value as to operate relay *c* which is set well above maximum full load.

Entirely separate from the relays described above are those installed for phase-to-ground protection. These are

e. One inverse time directional *C W C* relay, the upper pole winding of which is connected in the residual circuit of the 220-kv. line current transformers while the lower pole winding is connected in series with the lower pole windings of other similar relays to a current transformer in the 220-kv. station ground. While this relay is entirely selective, there is also installed for the more rapid disconnection of heavy current faults

f. One plunger type instantaneous over-current *S C* relay connected in the residual circuit of the line-current transformers. This relay is made directional by

g. One instantaneous directional *C W C* relay whose contacts are in series with *f*.

There is no back-up phase-to-phase protection to the 220-kv. lines, unless the overload relays on the transformers noted above were so considered, which of course clear the supply to the 220-kv. bus. However, it is expected that phase-to-phase faults will be extremely rare. Phase-to-ground back-up protection is provided by the use of

h. One low energy ground *C O* relay set higher than the main relay and connected in the residual of a second set of line-current transformers (on the other bushings of the oil circuit breakers) used for instruments. Its functioning operates a second trip coil. Thus this back-up relay comes into play should the regular trip coil fail. Also it operates first on faults involving small currents.

It is to be noted that the transformer overload relays are set selectively against the line impedance relays and transformer ground relay selectively against the line ground relays.

*Miscellaneous.* The 220-kv. structure is unique in that it contains the first installation of 220,000-volt lightning arresters ever made. They are of the oxide film type and consist of 666 disks per leg.

Communication with the Philadelphia load dispatcher is provided by two direct telephone lines, and in addition there are lines extending to the local (Darlington) exchange. Experiments are in progress using short wavelength space radio.

Fire protection is provided by water lines, carbon tetrachloride extinguishers, and a portable Foamite generator. In addition there are two stationary Foamite generators which can be connected to a system of piping for fighting fires in the main step-up transformer banks. Ordinarily this header is disconnected from the piping in the transformer bays but can be quickly connected by means of flexible hose. Water will be used to fight generator fires, easily connected links of hose being used to make the necessary connections.

The operating room is located at about the middle of the ultimate station and is provided with a pipe room beneath. Special consideration was given to lighting (both day and night) in order to avoid glare on the instruments. A skylight with a diffusing sash beneath is used.

Installed in the operating room are three semicircular switchboards arranged one behind the other. The first is a bench board, on which are mounted control switches and indicating lamps for the control of main and direct-connected auxiliary generators, step-up transformers, and 220-kv. oil circuit breakers and air-break switches. Back of the bench board is an instrument board on which are mounted the ammeters, voltmeters, wattmeters, reactive kv-a. indicators, etc., for the main circuits. Careful study was given to the location of equipment on the bench board and instrument board in order to facilitate accurate and easy operation. Back to back with the instrument board is a relay board on which are mounted the main protective relays. Around the rear and side walls of the room are located other boards for the control of the house service generators and transformers and for the voltage regulating equipment on the main and auxiliary generators.

250-volt control and emergency lighting is supplied from two 632-ampere hr. storage batteries and three 15-kw. motor-generator sets.

In line with the company's standard practise, telephone drop signals are used to indicate any occurrence that should be brought to the operator's attention.

Oil handling is accomplished by means of two 500-gal. per min. pumps located in the basement and five 12,000-gallon tanks located underground just outside the plant, together with an extensive system of piping. This consists of supply and discharge lines extended directly to the transformers and 220-kv. breakers, and conveniently near the 13.8-kv. breakers.

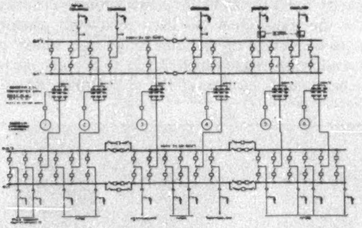

FIG. 7—SINGLE LINE DIAGRAM OF PLYMOUTH MEETING SUBSTATION

## PLYMOUTH MEETING SUBSTATION

The location of this substation about ten mi. northwest of the Westmoreland Substation was determined not only by the fact that it would be the terminus of the 220-kv. lines from Conowingo, but also for those of the interconnection with the Pennsylvania Power & Light and Public Service Electric & Gas Companies. The particular site chosen was directly alongside a heavy freight line (the Trenton Cut-Off) of the Pennsylvania Railroad, as this provided the necessary facilities for handling the very heavy apparatus involved in a substation of this character.

The function of the station is to step-down the energy received over the above 220-kv. lines to 66 kv., the existing high capacity transmission voltage of the Philadelphia Electric System, and to provide for synchronous condensers used mainly for stability purposes. Fig. 7 is a single-line diagram of this substation which may be considered in three parts, first, the 220-kv. substation with the step-down transformers, second, the 66-kv. substation, and third, the building housing the synchronous condensers and operating room. Figs. 8 and 9 show the plan and cross-section of it and Fig. 10 gives an artist's conception of how the completed substation will look. The area of land purchased is 40 acres.

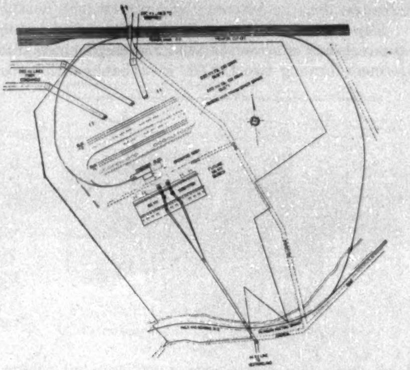

FIG. 8—PLOT PLAN OF THE PLYMOUTH MEETING SUBSTATION

The 220-kv. installation consists of two sectionalized buses, (Fig. 11) each line and transformer bank selecting either bus through oil circuit breakers. Provision is ultimately for seven lines and six transformer banks, of which three lines (two from Conowingo and one to the Siegfried Substation of the Pennsylvania Power & Light Company) and two 130,000-kv-a. transformer banks are being installed at this time. The oil circuit breakers are rated 1000-amperes, 187-kv., 2,500,000-kv-a. rupturing capacity. Each of the two Conowingo lines is provided with three 132-kv. potential transformers (the phase to neutral voltage of the 220-kv.

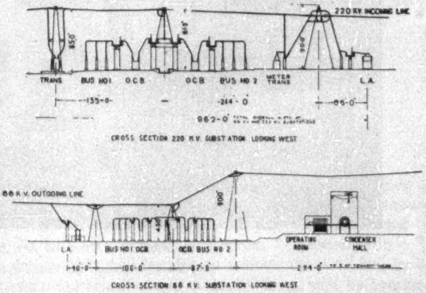

FIG. 9—PLYMOUTH MEETING SUBSTATION CROSS-SECTION

system being 127 kv.) These are used for impedance relays as well as instruments. The Siegfried line is provided with three combined current and potential transformer metering units, the potential elements of which are also used for relays and instruments. Each line is provided with a 220,000-volt auto-valve lightning arrester.

*Step-down Transformer Banks.* The initial installation consists of seven 43,333-kv-a. single-phase transformers forming two 130,000 kv-a. banks with a spare unit (Fig. 12). These transformers were originally rated at 33,333 kv-a. but will be increased in capacity by the application of air blown against the radiators. They have three windings: 220,000-volt, *Y*, 69,000-volt, *Y* and 13,300-volt, delta. The 13,300-volt tertiary serves the triple purpose of providing a closed delta for tap changing under load and for driving synchronous condensers. This tertiary is provided with a 33⅓ per cent tap for starting synchronous condensers. Transformers are equipped with inertaire equipment and weigh with oil 185 tons each. The tap changing under load has a voltage range of 15 per cent and in addition two five per cent taps are provided on the 220-kv. side.

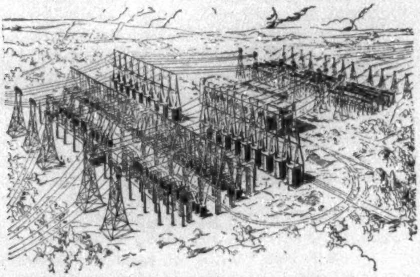

Fig. 10—Perspective Sketch—Plymouth Meeting Substation

Handling the heavy oil circuit breakers and transformers as well as the synchronous condensers was taken care of by a simple system of tracks shown on Fig. 8. A siding from the Pennsylvania Railroad extends in a wide sweep directly into the west end of the condenser building. At this point there is an assembly space large enough to hold a freight car and at the same time the complete transformer as is indicated in Fig. 13. In order to avoid excessive height for lifting the core of the transformer into its tank, a pit is provided in which the tank may be set and the core lowered into it. The transformer with the core inside is then raised to the floor level and its wheels put on the tracks which extend out into the switchyard. The 125-ton crane which is ample to lift the transformer with its core and oil, is also of ample capacity to lift the 30,000-kv-a. synchronous condensers. After the transformer has been completely assembled it is moved out of the building on its own wheels onto a transformer truck which is run to a point opposite the permanent location of the transformer, when the transformer is again moved on its own wheels into position. Numerous eyes are provided in the concrete in such a manner that hauling the transfer truck is readily accomplished by means of block and fall, and a small gasoline motor.

Switching off from the railroad track that leads into the condenser building is a track which extends through

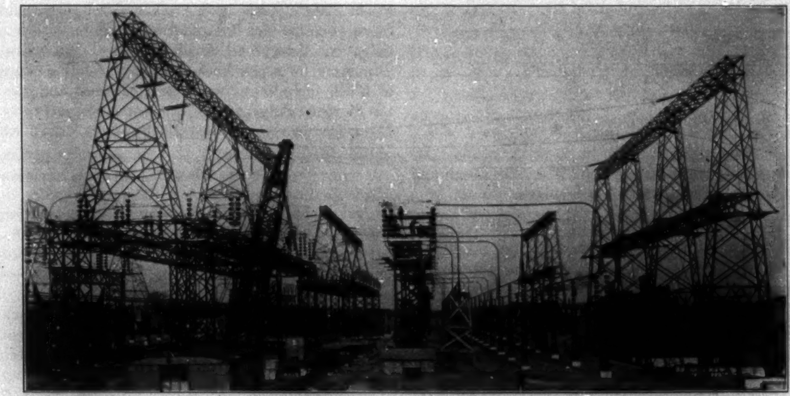

Fig. 11—General View of the 220-Kv. Yard During Construction

130,000-kv-a. transformer banks to the right, oil circuit breakers to the left.

the middle of the 220-kv. structure, which is used for handling the oil circuit breakers. Each single-pole element may be assembled in the condenser building and placed on top of a transfer truck; this in turn is placed on a second transfer truck. The breaker is then moved out to a position opposite its permanent location when the upper truck is rolled off the lower one until the oil breaker is in position. By means of jacks the breaker is lifted free from the truck and finally down on its I-beam foundations in a manner similar to that used at Conowingo. A track is also provided which will permit getting the potential transformers and metering units close to their location from which point they are skidded the short distance into position. It has been found on the initial installation alone the saving in handling heavy apparatus paid for the tracks and transfer cars.

*66-Kv. Substation.* The 66,000-volt substation is of practically the same design as at Westmoreland and the description of this latter given below will suffice. The only exception is that all of the lines at Plymouth Meeting are overhead, whereas most of those at Westmoreland are underground. Provision is made, however, for taking any of the lines from Plymouth Meeting out underground, though it is doubtful if this would ever be done. Initially this 66-kv. substation consists of sections for the two transformer banks, the two lines to Westmoreland and two lines to the Barbadoes Island Generating Station of the Philadelphia Suburban-Counties Gas & Electric Company at Norristown. Lightning arresters are installed on all four lines.

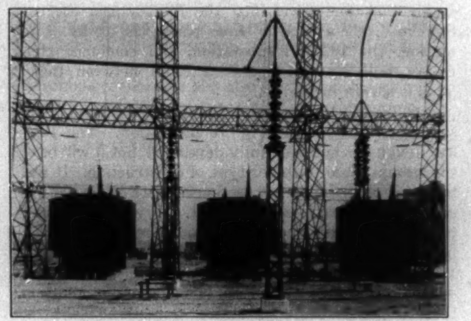

FIG. 12—130,000-KV-A., 220/69/13.3-KV. SELF-COOLED TRANSFORMER BANK

*Synchronous Condensers.* In addition to providing facilities for assembling transformers, oil circuit breakers, metering units, and potential transformers as described above, the condenser building is arranged to ultimately house six 30,000-kv-a. synchronous condensers. The building initially, however, is erected for three and three are being installed at this time.

These condensers operate at 600 rev. per min. and are provided with a scheme which gives extra high-speed excitation. This has been described in the technical press.[3] Each condenser is provided with a main 165-kw., 250-volt, six-pole, compound-wound exciter and a 40-kw., 250-volt, six-pole, compound-wound pilot exciter, one mounted on each end of the same shaft.

The condensers at this location are to be used primarily for stability purposes and will normally be carrying a light load. However, upon failure of one of the two Conowingo lines they will instantly supply the additional reactive kv-a. necessitated by one line operation as compared with two lines, and by holding up the voltage will materially stabilize the operation of the combined systems. This is accomplished by the regulator short-circuiting a resistance in the main exciter field causing the armature voltage to rise at a rate of 6000-7000 volts per sec. and applying a "ceiling" voltage of about 1000 on the nominal 250-volt fields of the condenser. It is planned to operate them normally at about 10,000 kv-a., though this may be varied in the light of operating experience. Under certain conditions they will be able to deliver about 55,000 kv-a. each and this increase of 45,000 kv-a. will be brought about in half a second.

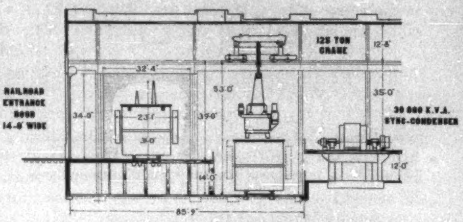

FIG. 13—PLYMOUTH MEETING SUBSTATION
Method of handling 43,333-kv-a., 220-kv. transformers

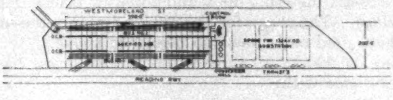

FIG. 14—WESTINGHOUSE SUBSTATION PLAN

The condenser starting and running oil circuit breakers are located outdoors between the transformers and the condenser building and from these are tapped

3. "Super Excitation," D. M. Jones, *G. E. Review*, Dec. 1927, p. 580. "Super-Excited Condensers," O. A. Gustafson, *Elec. World*, Feb. 18, 1928, p. 349.

off two banks of transformers which step-down to a 110-220-volt system for light and power supply.

In an extension of the condenser building is located the operating room with pipe room beneath. The section now built houses all of the 220-kv. switchboards and those controlling the synchronous condensers. Ultimately when the 66-kv. substation is further developed the operating room will be double in size to house the additional switchboards. At present the few panels required for 66-kv. control are located at one end of the present room. Two storage batteries and two motor-generator sets are used for supplying 250-volt control and emergency lighting.

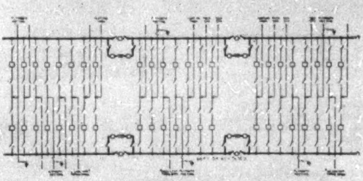

Fig. 15—Single-Line Diagram of Westmoreland Substation

To handle the large quantity of oil involved in this substation a separate building located a little distance from the main building and built partially under ground has been erected. In this house are located centrifuges, blotter press, oil pumps, and the system of valves and manifolds which will facilitate the rapid handling of oil. Five 12,000-gal. oil tanks mounted above ground are installed near this oil house and are used: one for clean circuit breaker oil, two for clean transformer oil, and two for dirty transformer or circuit breaker oil. Permanent supply and discharge pipes are extended to the 220-kv. circuit breakers and the transformers and to convenient points near the 66-kv. circuit breakers and 220-kv. metering units and potential transformers.

*Relays.* The relays for the 220 kv.-lines are the same as those used at Conowingo described above.

The 130,000-kv-a., three-winding transformer banks are provided with:

a. Three overload *C O* relays connected to current transformers located in the 220-kv. bushings. These will protect against phase-to-phase faults on 220-kv. bus, all faults on 66-kv. bus, and will act as back-ups to the 220-kv. phase-to-phase line relays.

b. Three special percentage differential *P Q Y* 28 relays with associated balancing current transformers. The large range of the ratio adjustment possible with these banks makes the use of a percentage differential relay necessary. The balancing current transformers combine the secondary currents from the 69- and 13.3-kv. windings and balance them through the relay against the secondary current from the 220 kv. side. They also serve to isolate electrically the current transformer circuits of the three windings, two of which are connected delta and the third star, and therefore, permit the use of standard grounding arrangement for the individual sets of current transformers. Due to the fact that there is no restraining action in the relay for transfer of power between the 69- and 13.3-kv. windings, it is necessary to use a special type of *P Q Y* 28 relay which is sufficiently insensitive to remain inoperative under the maximum possible case of such a power transfer, and also one which is sufficiently insensitive to prevent its operation on the initial rush of charging current when the bank is energized.

The 30,000-kv-a. synchronous condensers are provided with single winding *P Q* differentially connected relays.

The 66-kv. lines are equipped with duplex directional impedance *C Z* relays.

The station service transformer bank is protected by low energy overload *C O* relays.

### Westmoreland Substation

The Westmoreland Substation ties Conowingo and Interconnection power into the Philadelphia Electric System. It consists of three parts, the 66-kv. substation, the 13.2-kv. substation, and combined condenser building and operating room between them. This is shown in Fig. 14.

Figs. 15 and 16 give the single-line diagram and cross-section of the 66-kv. end of the substation. The 13.2-kv. design has not been fully developed, but it will be of the group-phase, outdoor type of construction. It will be noted that the 66 kv. section consists of double bus construction, each sectionalized at two points and provided for the future installation of reactors at these points. To each of the three sections themselves, two 100,000-kv-a. overhead lines from Plymouth Meeting will be connected or an ultimate of six, and in addition there is provision for a total of thirteen 50,000-kv-a. underground lines and four 80,000-kv-a. transformer banks, stepping down to 13,200 volts. The initial installation will consist of two lines from Plymouth Meeting, two lines to the Richmond Generating Station and two lines to the Schuylkill Generating Station, as well as two lines extending to some small (18,750 kv-a.) transformer banks at a nearby distribution substation, and two 80,000-kv-a. transformer banks. The oil circuit breakers are rated 800 and 1200 amperes (the latter on the Plymouth Meeting lines), 73 kv., 2,000,000

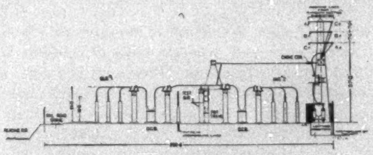

Fig. 16—Cross-Section of Westmoreland Station

kv-a. rupturing capacity. Lightning arresters are installed on the Plymouth Meeting lines. The relay protection consists of directional impedance *C Z* relays on all lines both overhead and underground, and differential *P Q*-21 with back-up overload *C O* relays on transformer banks.

The condenser building is laid out to house ultimately three 30,000-kv-a. synchronous condensers. They will be connected to the 13,200-volt bus bars and started by means of auto transformers. Two are being installed initially, operated at 720 rev. per min. It was felt that the speed of excitation on these units need not be quite as fast as those installed at Plymouth Meeting. However, fairly high speed is desired and this is provided.

While the weights to be handled at this substation are not as great as at Plymouth Meeting, nevertheless it was felt advisable to select a piece of land adjacent to a railroad and the present site with a siding from the Reading Railroad was decided upon. The siding extends along one side of the 66-kv. substation, through the end of the condenser building, on into the 13.2-kv. substation. A 100-ton crane in the condenser building will be used not only for assembling and repairing the synchronous condensers but also the transformers and other 66-kv. and 13.2-kv. equipment, which equipment can readily be brought into the condenser room by means of the above railroad siding and a transfer car.

Both the 66-kv. and 13.2-kv. sections as well as the condensers are controlled from one operating room which is part of the same building as the condenser room. This operating room is provided with a pipe room beneath. Adjacent and also part of the same building is an extension in which will be provision for 300,000-volt kenotron test set, offices, battery rooms, etc. A 15-kv. test set consisting of a transformer with ratio changing under load will be installed outdoors.

The 250-volt emergency lighting and control system consists of two 152-ampere-hour storage batteries and two 9-kw. motor-generator sets.

An oil handling system consisting of pumps and filters (both centrifuge and blotter presses) is provided, together with two 4500-gal. tanks located above ground, one for clean and one for dirty 66-kv. circuit breaker oil. Other tanks will be provided for the transformer banks. Supply and discharge pipes are extended conveniently to the 66-kv. breakers and directly to the transformers.

## Discussion

For discussion of this paper see page 906.

# 220-Kv. Transmission Line for the Conowingo Development

BY P. H. CHASE[1]
Member, A. I. E. E.

***Synopsis.***—*Current from the Conowingo plant is carried fifty-eight miles to the Plymouth Meeting Substation of the Philadelphia Electric Company over two 220-kv. single-circuit steel-tower transmission lines. These lines are carried on a right-of-way which provides space for a third future line. The conductors are 795,000-cir. mil steel-reinforced aluminum. Each circuit is shielded by two 183,000-cir. mil aluminum steel-reinforced ground wires. The insulator strings consist of 14 high-strength units in suspension position and 16 units in strain position. Conductors and ground wires are carried in a new type of slip clamp in order to decrease the unbalanced longitudinal stresses on the towers in the event of wire breakage. In general, foundations are of the earth grillage type. The tower design includes a number of novel features, among them the use of combination extensions to meet flexibly the varying topographical conditions, and the narrow waist immediately below the basket.*

FOR ultimate development, the 58-mi. transmission line to Philadelphia from the Conowingo hydroelectric plant on the Susquehanna River will consist of three 220-kv. single-circuit tower lines, each circuit supported in horizontal configuration. For the initial development two of the tower lines have been constructed.

The location of the Philadelphia terminus of these lines, the Plymouth Meeting Substation, approximately 15 mi. northwest of the center of Philadelphia, was determined by a number of factors, among them the practicable transmission routes into the main 66-kv. transmission system of the Philadelphia Electric Company, and the 220-kv. transmission line routes for interconnection with Pennsylvania Power and Light Company and Public Service Electric and Gas Company of New Jersey.

The location of the right-of-way is shown in Fig. 1. That portion of the right-of-way south and west of the crossing of the Pennsylvania Railroad at Glenloch passes through a fairly level farming country. North and east of Glenloch, the right-of-way follows the general direction of the railroads through Chester Valley, a natural channel leading to the Schuylkill River between Conshohocken and Norristown; thence to Plymouth Meeting Substation. This portion of the right-of-way passes through land of the highly-developed estate type.

After determination of the general location of the right-of-way by ground reconnaisance, an airplane map was made of a strip from 1½ to 3 mi. wide, to a scale of 1000 ft. to the inch. The airplane maps were used as a basis for the final location of the line and the determination of property owners and their holdings, from which final options were prepared for negotiation with owners of record. All these steps were taken prior to any negotiations or survey activities in the field. The right-of-way was secured on the principle of easements, being preferable to purchase in "fee simple."

The width of right-of-way was determined on the basis of accommodating three single-circuit tower lines, as shown in Fig. 2. The horizontal spacing between the conductors on a tower was largely determined by the clearance from the live hardware to the steel work, with the insulator strings deflected by wind and angles. A consideration of these factors resulted in a separation between conductors of 25 ft. 6 in. on tangent towers. In determining the distance between adjacent tower lines of 85 ft., or a distance of 34 ft. between adjacent wires, consideration was given to the safety

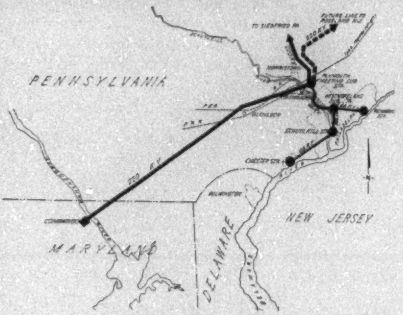

FIG. 1—ROUTE OF LINE

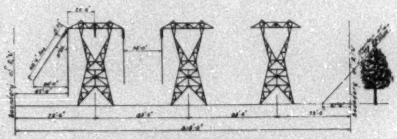

FIG. 2—CROSS-SECTION OF RIGHT OF WAY

of men working on a line adjacent to one in operation, conductor side-swing at center of span, and tower-offset.

The distance from each outside conductor to the edge of the right-of-way was determined by the amount of side-swing from wind, to which was added an additional factor for clearance.

In addition, a tree danger zone was considered to exist above a line starting from a point 45 ft. from the center line of the outside towers and extending upward and outward at an angle of 45 deg. Trees in this zone have been removed or trimmed.

### BASIS OF DESIGN

The following types of towers were used on the line:

Type A—Standard suspension tower, suitable for angles up to 1½ deg., 1100-ft. span.

Type B—Railroad crossing and angle tower, suitable for crossings, angles up to 6 deg., and tangent spans up to 2000 ft. This type, with a special top extension, was used for transpositions.

Type C—Angle tower, suitable for angles from 6 to 15 deg., and spans up to 1100 ft.

Type D—To be used for angles 15 to 60 deg., dead ends, and tangent spans up to 2500 ft.

In general, the line is designed to withstand a climatic loading of one-inch ice, but for unbalanced longitudinal load on the Type-A standard suspension tower, a tension in the conductor was taken corresponding to a load of ½-in. ice, it being obviously uneconomic to design for more severe conditions. Therefore, in order to minimize the stresses to which the tangent towers might be subjected under extraordinary conditions, a clamp of the releasing type was developed, to limit the maximum unbalanced longitudinal load on the tower to approximately 10,000 lb. Heavier ice loading was given consideration in the design of all types of towers for certain check conditions.

The design loads for the towers were calculated under the various assumed conditions of ice and wind for longitudinal, vertical, and transverse loading. These figures were increased by safety factors, thus giving maximum loads which the structural work of the towers was designed to withstand, using unit stresses shown in Table I.

The Type-B tower was designed to meet the requirements of General Order No. 13 of the Public Service Commission of Pennsylvania, which permitted its use for long tangent spans under non-crossing conditions when working to the allowable stresses in Table I.

The clearance diagram for the Type-A standard suspension tower is shown in Fig. 3. The clearance diagram was based on an ultimate string of 16 units and an arc control device having a probable transverse dimension of 24 in., and so located in the tower as to result in a normal clearance of 8 ft., a first accidental clearance of 6 ft. and a second accidental clearance of 5 ft. The first accidental clearance was on the basis of an 8-lb. wind, and the second accidental clearance on a 12-lb. wind, both without ice. Due to the lack of sufficient information on the probable shape and size of an effective arc control device, it was recognized that these accidental clearances might turn out to be liberal, but on the other hand, an arc control device larger than was assumed might be installed.

TABLE I

*Allowable Unit Stresses:*

Limiting values of slenderness ratio:

150 for corner posts
200 for web (computed stresses)
250 for braces (no computed stress)

Compression

$38{,}000 - 165\,\frac{l}{r}$ for values of $\frac{l}{r}$ up to 155,

maximum 28,000

$28{,}000 - 100\,\frac{l}{r}$ for values of $\frac{l}{r}$ from 155 to 250

Tension
30,000 on net section

Bolts
22,500 shear
45,000 bearing

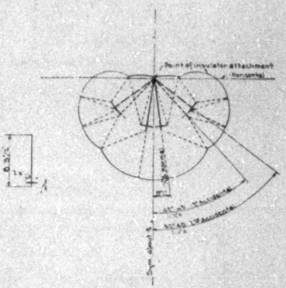

FIG. 3—CLEARANCE DIAGRAM FOR TOWERS, TYPE A

The length of span, height of tower, strength class of insulators, and characteristics of conductor must all be considered as a group, in order to determine the most economical combination and still maintain the most reliable service conditions obtainable. The size of conductor was determined by the electric loading conditions. This resulted in a conductor of 795,000-cir. mil aluminum steel-reinforced with a 40 per cent steel core, approximately 1¼ in. over-all diameter, which satisfied the corona requirements.

The conductor diameter being thus determined, and the ground clearance controlled by safety conditions, the over-all economics of tower height and span length were considered by studying various heights of towers, and for each height, increasing or decreasing the span to meet the catenary of the wire under consideration. The minimum ground clearance was 29 ft. 6 in.

## Towers and Foundations

Fig. 4 shows the assembly of the Type-A suspension tower. It is designed for one three-phase 220-kv. circuit,—the conductors in a horizontal plane with a separation of 25 ft. 6 in. Two ground wires are carried approximately 16 ft. above the plane of the conductors and midway between them. The lower section of the tower is square, so that the batter of the legs is the same in any face, resulting in a pyramidal section up to a point about 20 ft. below the conductors, where the sides flare outward to provide the necessary clearance for the middle conductor.

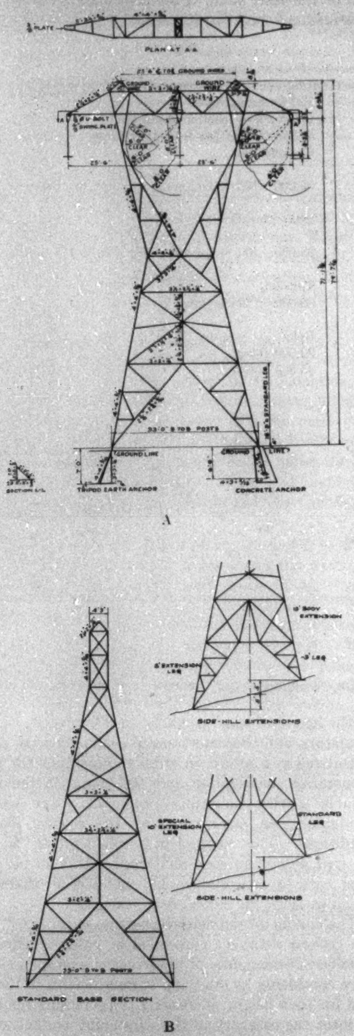

Fig. 4—Type-A Suspension Tower

Particularly on account of the size of the base, which is about 35 feet square, horizontal members close to the ground line are undesirable. To avoid this, the lower section is composed of four legs, each of which is independent, and may be made of any suitable length for small extensions and for uneven ground conditions. The standard legs are about 18 ft. in height, resulting in an 80-ft. tower, but special legs, both 5 ft. shorter and 5 or 10 ft. longer, have been used. As the connections are standard, any of these legs may be used on any one of the four corners of the tower.

For extensions greater than 10 ft., an additional section is inserted in the tower above the legs. By the use of the 15- or 30-ft. body extensions, the height of the tower may be increased by 5-ft. intervals to 125 ft.

Several new features of economic value are embodied in the tower. Maintaining the square horizontal section to as great a height as possible, (to the waist line) equalizes the distribution of the torque stresses in each of the four faces of the tower below the waist. The unbalanced horizontal shear at the foundation is reduced to a minimum by fixing the legs at an angle such that if extended above the waist line they would intersect at the center of gravity of the loads. The fact that the stresses are mainly in the tower legs permits very long equal or unequal leg extensions of the same size angle.

The net result is a tower and foundation that will have the lowest weight and cost for construction for the same loading-end strength, involving horizontal arrangement of conductors.

The towers are built from galvanized structural steel shapes, the largest main member for the Type-A suspension tower being 4 by 4 by 3/8-in. angle. Connections are all field-bolted with 5/8-in. galvanized bolts. The weights of all types of towers, extensions, and anchors, are shown in Table II.

For foundations, two designs were used; for normal line construction, a structural steel tripod anchor extending 7 ft. below ground; for special construction, a concrete foundation into which is placed an extension of the main leg angle. These two anchors for the Type-A suspension tower are also shown in Fig. 4.

There are three tranposition points, located at $^1/_6$, $^1/_2$, and $^5/_6$ points along the line. Fig. 5 illustrates the method of construction. There is a total of 520 towers, inclusive of the Susquehanna River crossing towers, in the 57.7 mi. of line.

Particularly because the design of this tower involved a number of novel features, load tests were made in order to check the soundness of the design assumptions. The tests verified the asumptions satisfactorily.[2]

TABLE II

Tower Weights

*Type A Tower—*

| | |
|---|---|
| Standard top section | 12,450 lb. |
| Standard "W" legs | 560 lb. |
| 5 ft. short "X" legs | 470 lb. |
| 5 ft. longer "Y" legs | 750 lb. |
| 10 ft. longer "Z" legs | 900 lb. |
| 15 ft. body extension | 3,540 lb. |
| 30 ft. body extension | 7,670 lb. |
| Earth anchors per set | 1,570 lb. |
| Concrete anchors | 430 lb. |

*Type B Tower—*

| | |
|---|---|
| Standard top section | 18,420 lb. |
| Standard "W" legs | 1,070 lb. |
| 5 ft. short "X" legs | 880 lb. |
| 5 ft. longer "Y" legs | 1,340 lb. |
| 10 ft. longer "Z" legs | 1,610 lb. |
| 15 ft. square extension | 4,830 lb. |
| 30 ft. square extension | 11,150 lb. |
| 45 ft. square extension | 18,700 lb. |
| 60 ft. square extension | 26,700 lb. |
| 75 ft. square extension | 36,100 lb. |
| Earth anchors per set | 2,180 lb. |
| Concrete anchors | 670 lb. |

*Type C Tower—*

| | |

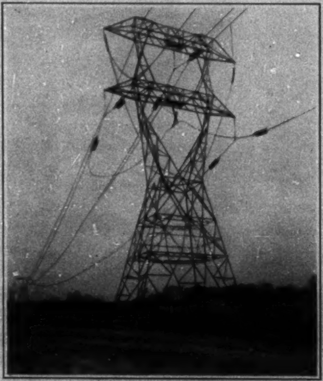

FIG. 5—TRANSPOSITION TOWER

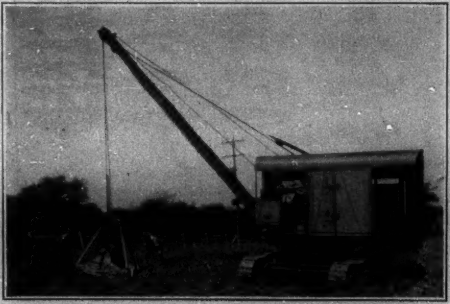

FIG. 6—CATERPILLAR TRACTOR CRANE

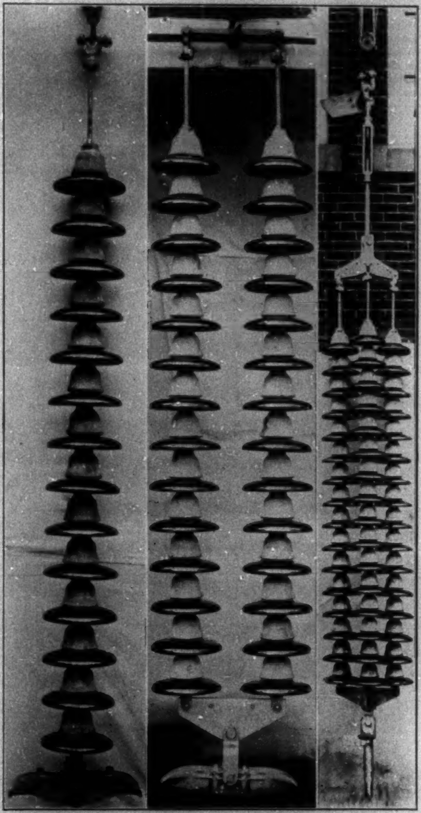
Considerable study was given to the characteristics of the steel-reinforced conductor, and the operating experience from all the major companies was carefully considered with special reference to eliminating troubles which have arisen in some cases from vibration of the conductor. Considerable investigation work has been done, both by the Philadelphia Electric Company, and the Aluminum Company of America in attempting to solve this problem. Investigation work indicated that when a metal is not under an appreciable initial strain it can withstand vibration practically indefinitely, but that its ability to withstand vibration decreases as the initial strain increases. This principle also applies to the aluminum strands of a cable.

---

[2] See article by R. W. Wilbraham, "Load Test Check Tower Design," *Electrical World*, Nov. 12, 1927.



A B C

Fig. 7—Insulator Strings and Clamp

Further investigation work on the modulus of elasticity of the finished cables has shown that the modulus depends upon the maximum tension which the cable has withstood. This is due to the fact that as the cable is stretched under tension the aluminum strands first share the strain with the steel until they are stretched beyond their elastic limit, at which time they take a permanent elongation. As the strain on the cable is released, the steel core, due to its greater elasticity, begins to pick up the strain and relieve the aluminum strands. This indicates the advisability of prestretching the cable. This pre-stretching secures two advantages, the first of which is indicated above in obtaining the reduction of the stress in the aluminum strands, and the second is that it establishes the modulus of elasticity of the cable, so that its characteristics, and consequently the sag, will not vary when the cable is subjected to a heavy ice and wind loading.

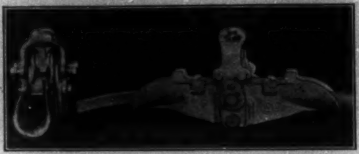


Fig. 8—Release Clamp

In a cable having a content of about 40 per cent by weight of steel, stress-strain curves show that after prestretching there is practically no tension in the aluminum strands under the ranges of temperature which usually exist at those times when vibration is most severe, namely, in fairly cold weather and with light winds. Experience has shown, further, that in practically every case where trouble has been experienced with broken strands, the steel content has been in the neighborhood of 25 to 30 per cent, and no strand failures with the 40 per cent content have been reported.

Fig. 9—Non-Releasing Clamp

In selecting the ground wire, it was concluded that it should be of the same general nature as the conductor, so that both materials would act in the same manner in unloading ice coatings; also that they should have approximately the same sag and swing characteristics. As an aluminum steel-reinforced cable was selected for the conductor, the same type of cable was selected for the ground wire.

Consideration also was given to securing a ground wire having sufficient current-carrying capacity to meet the requirements of lightning protection, and also to distribute any currents which might flow into the tower under the condition of an insulator flashover. It would have been possible to meet the above requirements with an all-steel galvanized cable, but a layer of aluminum strands outside the steel core has a preservative effect on the galvanizing, and consequently a cable with a steel core of approximately the same size as the conductor and carrying two layers of aluminum strand, was finally selected.

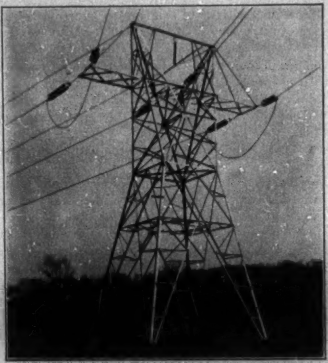

Fig. 10—Dead-end Tower and Jumper Construction

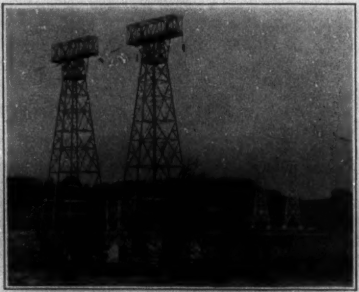

Fig 11—Susquehanna River Crossing

### Insulators and Hardware

The line is insulated with high-strength 10-in. disk insulators with 5¾-in. spacing. The design provides for an ultimate of 16 units for single and double suspension strings and 18 units for triple dead-end strings. The initial installation is with 14 units in suspension and 16 for triple-yoke strings, with a spacer link next to the tower having a length equal to two insulators, so that the conductors in every case are in the ultimate position.

The single, double, and triple string assemblies are shown in Fig. 7.

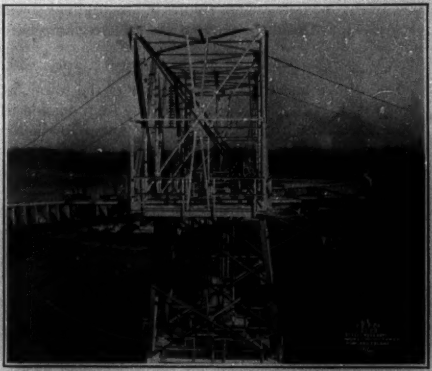

Fig. 12—Susquehanna River Crossing

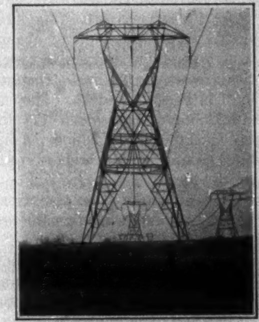

Fig. 13—Typical Line Construction

Except at points of special construction, the conductor and ground wire are carried in a releasing type of clamp, shown in Fig. 8. For special suspension construction, a non-releasing clamp as shown in Fig. 9 was used. Both clamps are of galvanized cast steel. In order to reduce the vibration-reflecting characteristics of the clamp they are free to swing in a vertical plane about an axis intersecting the axis of the conductor.

The releasing clamps are so designed that an unbalanced pull which will produce a longitudinal swing of 20 deg. of the insulator string will completely release the clamping mechanism. The wire is then held only by the friction in the saddle of the clamp. By the use of these clamps the longitudinal pull from a broken wire is restricted to a small fraction of the strength of the wire and under heavily loaded conditions should not exceed 5000 lb. This results in longitudinal tower stresses considerably less than if the release clamp were not used.

On the dead-end towers, the middle conductor is carried above and through the center of the tower, as shown in Fig. 10. The great distance from outside to outside of insulator string, for the center conductor made it impossible to support the jumper with a suspension string in the center and avoid the stranded conductor sagging to such a point as to decrease the clearances below safe limits. In order to maintain an economical design of tower top, recourse was had to carrying the stranded aluminum conductor in a 3-in. aluminum pipe, 24 ft. long. To each end was attached an aluminum reducing coupling carrying a 3-ft. extension of 1½-in. aluminum pipe from the end of which the conductor dropped free into the 90-deg. compression aluminum dead-end fitting.

Provision has been made for the attachment of arc control devices. A decision has been made to install some form of arc control device in the near future.

The transmission lines leave the power house on the west bank and are carried to the east bank in two spans —1450 and 2200 ft., respectively. The intermediate towers are located on an island in the channel of the river, and act as a dead-end and single tower, greatly diminishing the stresses on the roof structure. These towers are shown in Figs. 11 and 12. They are 228 ft. high (above the foundations), weigh 113 tons each, and have a base spread of 60 ft., supported on concrete piers 20 ft. above ground, with a bridge-type walk-way interconnecting the piers.

To provide communication from the river bank to these towers at times of high water, a cable-way of 1½ tons capacity has been installed.

The towers are of structural steel, the lower two-thirds riveted for rigidity, and painted with aluminum paint. The upper third is galvanized structural steel, bolted, in order to avoid maintenance painting adjacent to live parts. On the top bridge, on the crossarm of the towers, permanent rigging-booms have been provided, in order to facilitate maintenance operations.

The author wishes to express his appreciation of the helpful assistance in the preparation of this paper which was given by Mr. R. W. Wilbraham of the Day & Zimmerman Engineering & Construction Co. and Mr. W. W. Woodruff of The Philadelphia Electric Company.

# Discussion

## THE CONOWINGO DEVELOPMENT

(Wilson, Hentz, and Chase)

Baltimore, Md., April 19, 1928

**F. G. Baum:** The interesting thing about the Conowingo power station itself is the speed at which the work was done. It would have been very interesting if the authors had added the cost of this development.

I had occasion last year to look over a hydroelectric project in a foreign country where they had $6,000,000 to spend on the job, a much easier piece of work than this, and the job was laid out to be done in four years. I told them that they were losing two years in output and two years in interest charges.

The total result of the comparison is this, that while labor costs are about one-third of ours, when they get through building a power plant they have about as many dollars in the job as we have here. This results largely from the extra time taken to do the work.

I am very happy to see the eastern engineers finally coming to 220-kv. transmission. I believe that under that voltage we haven't any real transmission voltage, because the amount of power you can get even over a 110-kv. line is so small it is really a distributing line. We have had now, in northern California, five years' experience with 220 kv. Starting with 11-kv. lines built 30 years ago and extending up gradually to the 220-kv., the 220 was the first line we built that surpassed our expectations. Previous to that we were always more or less disappointed in our transmission results, and not only in the amount of power but in the security of service. Very often it is figured that the exposure from service interruption depends on the number of miles of exposure, but what you really are interested in is the number of interruptions, say, per million kw-hr. delivered, and that certainly is going to be much less at 220 kv. than at 110 or lower voltages.

I believe that the system adopted for this transmission was the one solution which was right; that is, the decision for a *constant* voltage system brought about by synchronous condenser voltage regulation.

**F. C. Hanker:** The problem of the Conowingo System is largely one of insuring, in so far as possible, continuity of supply to the ultimate user. That problem, when you come to the larger power plants, located some distance from the load center, involves the additional link of transmission. As Mr. Baum has pointed out, the records on the Coast have shown very satisfactory results on the higher voltages. There has not been the same period of operation in the East, but surely, with the amount of engineering talent applied to the problem, we can expect that after some of the initial troubles are overcome satisfactory service will be secured.

In the Conowingo Development, fortunately, we had the benefit of a number of years of analytical work and field testing combined with the experience on the pioneer work of the West on longer lines. The studies indicated that a very considerable improvement in the operating results could be obtained by special characteristics in the apparatus to improve operating stability.

Those improvements in the characteristics of the apparatus have been made possible to a greater extent on some of the Coast propositions where the generating capacity and the accompanying equipment do not represent as large a percentage in the total investment. In those cases you can afford to put considerably more expense into apparatus than in the ordinary case where the generating and regulating apparatus is a smaller proportion of the total cost.

There has been theoretical discussion on load limitations of systems and the problem is becoming more generally recognized. What we need now is more operating experience with apparatus having improved characteristics and the results of the next few years will show the justification for the expense involved.

**R. L. Thomas:** Mr. Wilson in his paper has referred to one feature of the Conowingo development which is perhaps unique, namely the backwater or pond-level agreement with the Holtwood development of the Pennsylvania Water & Power Company. The details of this arrangement belong in the field of civil rather than of electrical engineering but a number of questions has been asked and a brief statement regarding the scheme may be of interest.

The Holtwood Development is located in Pennsylvania about 15 mi. upstream from the Conowingo Development. When the Pennsylvania Water & Power Company took over this development and completed the initial installation in 1909 and 1910, the tailrace as planned was already completed. The plant has been located at the upper end of an island, forming a natural tailrace consisting of a very irregular, deep, and narrow channel about two-thirds of a mile in length. When unwatered it looked like a gorge. No improvements had been made on it. Below this natural channel there was originally a reef which formed a rapids about half a mile long, ending in another deep pool. These deep pools are rather characteristic of the Susquehanna. Through that reef the McCall Ferry Power Company had cut a canal, but they left what amounted to a flat rock weir at an elevation of 101½ ft. above mean sea level for the purpose of sealing the draft tubes of the turbines. Also their canal was designed for a flow of 20,000 cu. ft. per sec., whereas the Holtwood power house, as subsequently developed, actually discharges 30,000 sec.-ft. at full load. This increased discharge and the naturally poor hydraulic characteristics of the tailrace resulted in a maximum drop through the tailrace of about 14 ft. at full load with no water flowing over the Holtwood Dam. This represents a lot of power, and obviously it was economical to try to regain as much of it as possible.

In 1916 the company started on an ambitious excavation scheme, calling for a large amount of subaqueous rock excavation. Naturally the power house could not be shut down and on account of the swift current the work involved was expensive and difficult. It was suspended in 1917 on account of the War. About the same time studies were being made of the Conowingo project, the estimates being based on a clear-crest dam with crest at an elevation of about 100 ft. above mean sea level. Studies made at that time showed that a method of developing the loss in the Holtwood tailrace more economically than by excavation would be to superimpose steel gates or a movable dam of some kind on the Conowingo dam so as to maintain a water level there considerably higher than had been contemplated previously, and thus back water into the Holtwood tailrace and partially "drown out" the rapids there with, of course, some consequent loss in head at the Holtwood plant. In effect the proposition was to transfer a varying amount of head from one plant to the other. Roughly, the general order of magnitude of the ratio of gain at Conowingo to loss at Holtwood was about 10 to 1.

Those studies were made on the assumption that both projects would be controlled by the same interests. Later when the Conowingo project was undertaken by the Philadelphia Electric Company, engineers of both companies made exhaustive studies and again showed that there was a very considerable gain to be accomplished by maintaining a pond level at Conowingo considerably higher than would be allowable under a scheme which would permit no interference with levels at Holtwood, or under a scheme adhering to the provisions of certain agreements made years before. A dam of this type is logically a movable-dam proposition, as property or flowage rights must be acquired anyway to elevations above the maximum flood levels. Also when the Conowingo engineers adopted the lower site at Conowingo it was found that a movable dam or gates of some type were almost necessary, or at least economical, in order to hold down the pond level at time of maximum flood to such an elevation as would permit a feasible railroad grade from the Conowingo dam down to Perryville.

An arrangement was finally entered into between the two companies whereby the lower company maintains a pond level not to exceed 108½ ft. above mean sea level. This amounts to a sale of raw water power, you might say, from one company to the other, and I think both companies are going to account for it as a sale of power. The lower company pays the upper company its loss (meaning the loss under the present tailrace conditions, and not the greater loss which would have obtained if the excavation had been carried out) plus a share in the gain at Conowingo. It is a good proposition for both companies, and obviously it is in the interests of conservation of natural resources, because the desideratum is to get the most possible energy out of the Susquehanna River from the Holtwood pond to the Conowingo tailwater, and various computations have shown, depending upon what assumption is made, that the over-all, average net annual gain is from 84,000,000 to over 100,000,000 kw-hr.

Now the overlapping of heads between plants on the same stream, and operated by the same company, is not new, as it has been practised by several companies in recent years, but I believe that such an arrangement between two independent companies is unique, and it is gratifying that what was evidently a good engineering proposition could be put through in a business way.

The Gould Street engineers state that they adopted 440-volt auxiliaries in order to eliminate having two voltages and because the cost of the motors was actually less. I wonder if Mr. Hentz would care to say something on that.

As to the economic side, these papers make the situation clear. Before the Conowingo project was carried out there was available in the lower Susquehanna, from Holtwood down, a fall of about 100 ft., most of which was capable of development, but such development would be economical only if a market could be found which, first, would be large enough to permit of a great over-development of the river as compared with what is generally called firm power; second, would be large enough to absorb practically all of the available output from the start; and third, with a leak load sharp enough to give the hydro plant a high-capacity value. Baltimore, with a large existing supply of hydroelectric energy, did not offer such a market. Philadelphia did, especially with the transmission interconnections. It certainly is to the interest of the public that this power which has gone to waste for all time should be developed, thus saving, I believe Mr. Wilson stated, about 750,000 tons of coal a year.

**P. L. Alger:** I have been much interested in the design of four of the main Conowingo generators. They were so large that they were assembled completely at the plant, and no tests were made at the factory. I am glad to say they have gone into service without any important difficulty, and seem to be operating very well.

One of the novel features of the design of these machines is that the rotor rims are made of overlapping steel plates wrapped flatwise around the periphery, and the rotor spider arms are made of steel plates riveted together, so the entire rotor, except for the hub casting, is of plate construction. This is the first time, I believe, that such a construction has been employed. It has been described in a recent A. S. M. E. paper[1].

After the tests on the machines are completed, we hope to publish a paper giving the general dimensions and details of performance. At the present time, our expectations are that the efficiency at full load and 0.9 power factor under rated conditions, will be 97.5 per cent, although the short-circuit ratio is exceptionally high, approximately 1.4.

**D. W. Roper:** I should like to inquire from the authors of the papers if there were any special features in the contract which offered an inducement to the contractors to make speed?

**A. F. Bang:** I wish to offer a slight criticism of the high-tension switching layout at Conowingo. It may have been the most economical layout for the present to put all switches on top of the roof, but it seems to me that such an arrangement very decidedly limits the expansion possibilities. This would be especially undesirable in case at some future time it should be considered important to tie in another high-tension circuit, besides those going to Philadelphia.

---

[1] H. G. Reist, "Plate-Steel Rotor for an Electric Generator." Paper presented at the Spring Meeting, 1928, of the A. S. M. E. at Pittsburgh, Pa.

Another questionable feature seems to me the ever present danger of oil-switch fires. These will happen occasionally, as we all know, even with the best of modern switches. And in case they do happen, is there not appreciable danger to the extremely valuable equipment below, at least far more so than in a layout where the switching station is at some distance from the power house?

**Alex. Wilson:** As to the speed with which the construction work was completed, there were several contributing factors, one of which was good fortune in respect to damage and delays due to floods. While two of the floods which occurred during the period of construction exceeded the previous records for the respective months in which they occurred, the condition of the construction work at the time the floods occurred was in such shape that but little damage was done.

Another and probably the most important factor contributing to the speed of construction was the careful scheduling of all operations and rigid adherence to the schedules. These schedules went into great detail, scheduling issue of drawings and the ordering and delivery of material, as well as the actual operations of construction; the calendar period in which each operation must be performed was likewise clearly defined and from time to time as the work progressed, the progress schedules were revised and where gains were made in any of the major operations, the schedule of such operations was advanced.

No bonuses were offered to the contractors to make speed. All of the contracts were agency agreements under which the contractor received a fixed fee for his services.

Mr. Alger referred to the efficiency of the generators. The efficiency of the water wheels might also be of interest. At best gate, these wheels have an efficiency of about 92 per cent.

**R. S. Hentz:** Mr. Bang has asked why we put the substation at Conowingo on the roof. That was primarily a matter of economics. The contour of the land was such that we could not have erected a substation in any other place except by going up on top of the hill where a double-bus substation could be erected. We believe a fair degree of flexibility has been incorporated into this 220-kv. layout. There is provision for one more 220-kv. line, making three in all. As two lines will easily transmit the contemplated maximum ultimate development of the station there was no need to provide for further expansion. True, it would have been better to have had a double-bus layout similar to that at Plymouth Meeting, but it would have cost too much at Conowingo. Plymouth Meeting, in addition to controlling the power from Conowingo, also controls that from the interconnection, thereby making it of greater importance and fully justifying a double-bus layout.

In regard to the matter of oil fires, when a satisfactory switch is developed, not using oil, we will be very glad to look at it. However, oil switches are with us and we have to use them. In the case of the 13,800-volt switch structure, the building has been divided into several comparments by smoke-proof barriers, thus confining any oil fires that may occur.

In regard to the lightning arresters, there is one other factor I think was not touched upon. The generators are provided with over-speed and over-voltage devices, (the over-speed is mechanical). These two devices have their contacts in parallel, so that the closure of either will trip the generator breaker. This is necessary to protect any motor driven equipment that might be left on those machines from damage due to excessive speed. This also protects the lightning arresters from very high voltages.

**P. H. Chase:** I was asked to say something about the lightning situation and the selection of the ground wires on the transmission lines. This matter of ground wires received consideration from many different angles. When we first started there was no operating experience with 220 kv. to help us on the lightning conditions in the East. The initial decision was to omit ground wires. However, before the project was very far under way there was some operating experience in the East, in northern Pennsylvania, and also considerably more information was developed from theoretical and experimental work which indicated the advisability of installing ground wires. The decision was therefore made to include ground wires. There have been various estimates as to how much the induced voltage would be reduced by the use of ground wires; as high as 50 per cent has been talked of. The percentage reduction in voltage is still largely a matter of speculation. I think that in another year we will be able to give quite conclusively the results as they affect operation. We have been through one lightning storm this spring that crossed the line without causing any trouble.

Mr. Hentz mentioned a high-voltage test. Observing the line during this test I was quite surprised that it didn't show much visible corona at 380,000 volts. There were streamers, spots along the conductor, and looking along the conductor one could see a bluish haze. Also there was a slight amount of corona on the line end of the strings. Photographs were taken of the insulator strings with quartz-lens cameras, taking advantage of the ultra-violet rays, but very little corona was in evidence.

It may be of interest to hear of a few questions that have come up since the line has been in service. A few weeks ago we got a complaint from one town that automobiles passing under the line were being "charged," and also that there was serious trouble with radio reception. It turned out that all those were unfounded and simply made good newspaper stories. The starting point was apparently trouble from some trolley circuit or something like that. Complaints have been received that the wires are dangerously close to the ground. When you stop to think of it, to the layman a conductor 1⅛ in. in diameter looks considerably nearer at 30 ft. than, say, a No. 6 A. W. G. wire.

Those were very amusing, although they had to be met and answered when our publicity people called them to our attention.

# The Communication System of the Conowingo Development

BY W. B. BEALS[1] and E. B. TUTTLE[2]
Member, A. I. E. E. Member, A. I. E. E.

***Synopsis.***—*This paper describes the communication system which has been installed to serve the power plant at Conowingo, Maryland, and its associated transmission line.*

*The important features to be considered in designing a telephone system for a power plant are pointed out. The types of telephone switchboard and telephone instruments chosen in this case to meet the special requirements of the generating station, together with the layout and cabling arrangement, are outlined.*

*The paper also discusses the possible ways of providing for the needs of the load dispatcher and the plan adopted at Conowingo; the facilities provided the patrolmen for calling from points along the transmission line; the connection from the private branch exchange to the general telephone system; and the special electrical protection installed on the long lines leaving the power house.*

## 1. INTRODUCTION

THE proper functioning of a power plant and distribution system depends to a large extent upon the ability of the operating force to communicate easily and promptly with one another. Therefore, the details of design of a power system may be influenced by a consideration of the various possibilities of telephone communication.

The design of a telephone system to meet the needs of a generating station such as that at Conowingo and the transmission network associated with such a system, requires the closest cooperation between the power and telephone engineers and a thorough understanding of each other's problems.

Among the important features to be considered in this cooperative work are:

a. Continuity of service.

b. Means for quick communication with any part of the generating station.

c. Location of telephones so that they can be used without taking power-house employees away from their working stations.

d. Means for communication between the generating station, system operator, and points along the transmission line.

e. Protection for the circuits connecting with the general telephone system.

All of the features in the above list were given very careful consideration in designing the telephone system for the Conowingo project.

The essential elements of such a telephone layout consist of a private branch exchange switchboard which provides convenient means for connecting a telephone in one part of the plant with a telephone in another location or with telephone central offices; telephone distribution cables running from the switchboard to the locations where the telephones are installed; circuits running from the branch switchboard to the central office of the telephone company; and finally, the telephones themselves so located as best to meet the needs of the people who are to use the system.

## 2. PRIVATE BRANCH EXCHANGE AND ASSOCIATED POWER PLANT

(a) *Conditions to be Met and Type Adopted.* The Conowingo power house is located within the area served by the Darlington, Maryland, Central Office. In the Darlington central office area, the service is of the magneto type (*i. e.*, hand generators are used for signaling and dry cells are installed at each telephone set to supply talking battery). In such an area it is usual to furnish private branch exchange equipment of the same type. At the Conowingo power house, however, in view of the size of the installation and the fact that it lends itself better to some of the rather special arrangements needed at certain places in the power house, it was decided to use the common battery type of telephone system where the telephone user signals the operator by simply lifting the receiver off the hook.

The adoption of the common battery type of private branch exchange in the Darlington central office area necessitated certain modifications in the usual type of switchboard in order to furnish lamp signaling and supervision and at the same time to operate on connections to the magneto central office switchboard at Darlington.

The operating battery consists of eleven cells of the enclosed radio type and is kept in a fully charged condition by a small, full-wave rectifier, operated from the local lighting circuit and adjusted to trickle charge the battery continuously. The battery has sufficient capacity to operate the telephone system for some time in case of trouble with the rectifier or the local lighting circuits.

Regular and emergency ringing interrupters are installed for supplying energy to ring the various tele-

2. Engineer of Transmission & Outside Plant, The Bell Telephone Company of Pennsylvania.

*Presented at the Regional Meeting of the A. I. E. E., District No. 2, Baltimore, Md., April 17-19, 1928.*

phone stations and the central office of the telephone company. A hand generator is also installed in the switchboard for emergency use.

Alarm signal equipment, consisting of a bell and lamps, is provided to indicate the operation of a charge or discharge fuse on the battery, the failure of the a-c. service or the burning out of a rectifier tube. Spare fuses and rectifier tubes have been conveniently located for replacements in case of failure.

(*b*) *Location and Layout of Private Branch Exchange Equipment.* The private branch exchange switchboard is installed in the main control room and adjacent to the power switchboard operator's desk, so that it can be operated by the power switchboard operator when desired. It is equipped for handling 70 common battery lines, 10 local battery lines and 5 central office trunk or long tie lines (such as lines to Philadelphia). Provision has been made for further trunk and tie line growth.

In the usual private branch exchange all relay and signaling equipment is contained in the telephone switchboard framework. The modifications at Conowingo required a number of additional relays and repeating coils which the switchboard would not accommodate. These relays and coils have been mounted on a small rack similar in design to those used in small telephone central offices. Since the ultimate layout of the main control room would not permit the installation of this rack adjacent to the telephone switchboard, it has been placed in another room as close as possible to the board.

From the telephone switchboard lead-covered cables extend to a cross-connecting main frame which permits the association of any cable pair in the distributing cables to the telephone stations, or, in the cable leading out of the power house, with the proper switchboard terminal. The distributing frame is of the type used in small telephone central offices and carries the standard telephone protectors. It has been located in the same room assigned to the telephone power plant. This room is close to the center of distribution of the telephones which will ultimately be needed and will, therefore, permit of the most economical distribution cable layout.

### 3. TELEPHONE STATION EQUIPMENT AND DISTRIBUTION CABLE

(*a*) *Requirements and Types Adopted.* As mentioned previously, the main requirements of the apparatus to be installed in the power station are simplicity of operation, durability and compactness. The first of these has been met by the adoption of common battery signaling equipment. To meet the second and third conditions the telephones have been placed in recessed cabinets in the walls. Each cabinet is designed to hold a standard desk stand and bell box and is provided with a door which lets down to serve as a shelf when the telephone is in use. When the telephone is not in use, the door is kept closed and the apparatus is out of the way in a protected location. This method of installation is general in the power stations and substations of the Philadelphia Electric Company.

At the gage board at each of the machines, under certain conditions it will be necessary for attendants to take orders over the telephone, read the meters, and adjust apparatus at the same time. In order to meet this condition and still avoid the possibility of having telephone apparatus in a position where it might be in the way, a jack has been provided at each of the gage boards, and operators' telephone sets with chest transmitters and head receivers with extension cords have been provided in convenient locations for use with the jack ended circuits. The jacks are enclosed in dust-proof boxes and are connected to two circuits terminating on the switchboard, one circuit terminating at the panels for service generators Nos. 1 and 2 and main generators Nos. 1 to 4 and the other circuit at the panels for present and future main generating units Nos. 5 to 11. With this arrangement the station attendants can talk over the telephone and yet have both hands free for whatever they are required to do.

Telephone stations have been provided along the dam for use in making reports from points in the vicinity of the gates. Since these stations are in locations which will always be subject to a certain amount of moisture, mine type sets have been installed in recessed cabinets located at convenient points along the parapet wall. These cabinets are provided with metal frames and covers and are kept locked in order to prevent use of the telephones by unauthorized persons. Mine type sets have also been provided on the observation platform near the spillway and in the inspection tunnel in the vicinity of the butterfly valves.

Five mine type sets have been installed on the steel framework of the substation located on the roof of the power house, some points of which are 85 ft. above the level of the roof. They provide a means of communication with men working on the 220-kv. disconnecting switches. Four additional mine type sets have also been installed at various locations on the roof of the power house. In addition to these telephones, four jack-ended circuits have been mounted inside of the mine type sets on the roof. Durable, moisture proof extension cords terminated at one end in a plug for connection to the jack-ended circuits and at the other end in a small jack box have been provided for the use of men working on the inside of the 220-kv. circuit breaker tanks. The jack boxes are arranged to be attached to the workmen's belt in order to leave both his hands free. A regular telephone operator's set with a short cord and plug is provided so that the workman may insert the plug in the jack box on his belt. This gives an easy means of communication between the men working in the circuit breaker tanks and men outside.

In the office bay, standard desk set equipment has been provided for office employees.

(*b*) *Cabling Layout.* In view of the conditions to be met in rendering telephone service in power stations, the telephone circuits are for the most part in lead-covered cable except that the runs from cable terminals to the individual stations are made with single pair twisted wire. These cables vary from 11 to 101 pairs each and are run through metal conduit, installed for this purpose when the concrete of the structure was poured. The telephone conduits are separated by several inches from the conduits carrying lighting and other distribution circuits in the power house, and are bonded to the power system ground so that in case of any faults on the power circuits it is expected that resulting voltages and stray currents will not introduce a hazard on the telephone circuits. The installation of telephone cables of the size employed in the power house necessitated placing "pull boxes" at frequent intervals along the conduit runs.

The distribution cables to the stations are terminated in five main terminal boxes where the individual cable pairs can be connected to the wires running to the various stations. This permits of considerable flexibility in cable pair assignments, and makes it possible readily to interchange cable pairs in case one becomes defective or to replace a short section of cable without interfering with the rest of the circuits in the telephone plant.

### 4. Outside Lines

(*a*) *Trunk Lines and Outside Stations.* The private branch exchange is connected with the telephone company's central office at Darlington, Maryland, by means of two circuits which are carried out of the power house in lead-covered cable and thence by open line wires to the central office. The same cable carries a few lines to stations located in the employees' houses not far from the dam.

(*b*) *Load Dispatching Circuits.* In any power transmission system the operations requiring coordinated action at power sources and substations make it imperative that communication be established quickly and maintained without interruption between the load dispatcher and the operating units.

As the system is extended to include more than one source of supply the necessity for this close supervision on the part of the load dispatcher is very greatly increased by the need for proper distribution of loads. This supervision may be secured by automatic operation or through communication with an operating force.

At the A. I. E. E. Midwinter Convention in Philadelphia in February 1924, two papers were presented describing apparatus for distant operating by mechanical means. The use of this equipment places in the hands of the load dispatcher the means of regulating generators and loads by his own personal actions and in certain cases generating plants and substations can be very satisfactorily operated in this manner. Associated with the mechanical operation of these systems there must be visual indication of their conditions by such means as distant metering, gaging, etc.

With power units and substations of such size as are involved in the Conowingo project, personal attendance becomes imperative for a number of reasons, and therefore system operation from a distant point through mechanical agencies was deemed not suitable for this installation.

Several methods which present themselves, *viz.*, telephone, telegraph, and printing typewriter were considered in setting up the load dispatching system for the Conowingo power project. The extensive existing load dispatching system of the Philadelphia Electric Company system had a great influence in deciding what extensions should be made to care for the interconnection with the Conowingo project. This existing system consists of private lines leased from the telephone company and connecting the various substations and generating centers with the general office building of the company. At this location the lines terminate in a magneto switchboard in the office of the load dispatcher who can thus secure instant direct contact with the various units of the system.

This system is reserved for the exclusive use of the load dispatching forces and no connection is provided to the telephone company's exchange system except through an emergency circuit on the board in the load dispatcher's office.

Direct telephone company facilities were, therefore, found most suitable in the extension to Conowingo of the load dispatching system. In planning this extension, two prime factors were considered to be highly important, continuity and reliability of service. To provide for the former, it was decided to supply both regular and emergency circuits routed through separate cables or over separate pole lines so that in the event of ordinary maintenance troubles which might affect one circuit, the second would be available. The reservation of both of these circuits for load dispatching exclusively is not warranted, and provision is made for one to be used between the private branch exchanges provided for general telephone business, but to be available to the load dispatcher by means of loop jacks in his private line switchboard. This latter arrangement permits the load dispatcher to take over the use of the second circuit and clear any conversation that it may be carrying.

The second requirement, reliability, presented the more difficult engineering problem, as it will in any similar situation. The telephone company had existing plant for the entire distance from the Conowingo site to the headquarters of the Electric Company at 10th and Chestnut Streets, Philadelphia, consisting of underground cable plant between Philadelphia and Havre de Grace at the mouth of the Susquehanna River connected to an open wire pole line from Havre de Grace to the power site. Underground plant is, of course, most reliable, but the open wire line may be interrupted during heavy sleet and wind storms.

The power company has a continuous private right-of-way from Conowingo to Plymouth Meeting. This right-of-way is free from trees and other obstructions, but proximity to the high-voltage transmission line rendered it unsuitable for communication circuits.

Various means of securing telephone service were studied, including carrier current systems on the power transmission lines and short wave radio. At the time this paper was prepared, consideration was being given to the desirability of building a new pole line on a private right-of-way, cleared of trees and shrubs, from Havre de Grace to the power site. The poles and wires would be so spaced and of such strength as to be capable of withstanding ice and sleet loads such as have been encountered in the past.

While load dispatching is of prime importance in setting up communication service, there are other important uses which cannot be neglected. Many routine matters of operation and maintenance can best be handled by telephone and facilities to do this must be provided. Many power companies do not feel that it is necessary to reserve the dispatching circuits exclusively for that service and use the same circuits for the transaction of general business. However, with the demand on the power companies for continuous service by trunk line railroads and city water supply systems, etc., the necessity of immediate communication for load dispatching purposes becomes more exacting. For this reason the Philadelphia Electric Company decided to provide a second circuit to care for general business and make this second circuit available in emergencies for load dispatching purposes as outlined above.

(*c*) *Patrol Stations.* Another important communication service is that provided for the use of patrolmen. Regular telephone service by means of telephone stations connected to the nearest central office of the telephone company offered opportunity for patrol service over the regular toll lines of the telephone system. With the increased speed of service now provided over these lines dependable and rapid connections can be obtained. This method has the advantage over a single patrol circuit, in that in case of failure of one toll line, alternate routes are available. If the number of patrol stations is small and the calls infrequent, this service is also less expensive.

This method was adopted for the Conowingo system and four patrol stations have been established between Conowingo and Plymouth Meeting, each with the telephone located in a building owned by the Power Company and located on its right-of-way.

(*d*) *Special Protection.* Preliminary computations indicated that at time of fault on the 220-kv. transmission line, ground currents of considerable magnitude would flow through the station ground connection, and even if the impedance of the ground connection were as low as a fraction of an ohm, there would be a considerable rise in ground potential in the neighborhood of the dam.

A rise in ground potential at the dam with reference to the ground at the other terminals of the circuits connected to the private branch exchange might operate the telephone protectors and result in interruptions to telephone service at times when it was most needed. These potentials would also be effective between the telephone circuits and ground in any location outside the area affected by the power system ground.

Since all metallic structures in the power house are thoroughly bonded to the same ground; no potential will exist between telephone equipment and other metallic structures in the power house unless the telephone be connected metallically to a circuit extending outside the area within which a considerable difference in ground potential is caused by the fault.

Due to the extensive grounding system, consisting of ground plates, water pipes, the steel reinforcement of the dam itself, and numerous other metallic structures in the power plant, the most practical method of avoiding interruptions to service coincident with failures on the power line seemed to be, in this case, to isolate the portions of the long circuits within the area in which potentials considerably different from outside points might be expected.

Tests were made jointly by the power and telephone interests to determine the impedance of the power system ground connection and the extent of the area which might be at potentials substantially different from those at distant points. These tests were made by feeding current through a ground established at some distance from the power station back to the power station ground and measuring the difference in potential between the power station ground and the telephone central office grounds at Darlington and Belair, Maryland, as well as at intermediate points. These tests indicated that the impedance of the power system ground was at that time between 4/10 and 5/10 of an ohm and that the potentials of points along the west bank of the river and in the Stone and Webster company's construction camp close to the dam varied only about three per cent from the potentials impressed on the power station ground. It was also found that the potential of the water system in the power company's village about 3000 ft. from the dam was only about 6 per cent lower than the potential at the dam and that the potential at points in the village about 100 ft. away from the nearest water pipes was only about 15 per cent different from the potential at the power plant. Further measurements indicated that the earth potential gradient along the telephone line toward Darlington central office was quite gradual and a slight rise in potential was noted even at the Darlington central office, more than two miles from the dam.

A point about a mile away from the dam at the edge of the power company's property where the circuits to the private branch exchange leave the telephone company's line was selected as the most practicable location for insulating transformers to be used in isolating the telephone plant in the area within which substantial rise in ground potential might be expected. The measurements indicated that about 65 per cent of the total drop in potential occurred between this point and the power station ground.

Western Electric Company's No. 50-A repeating coils, insulated between windings for 25,000 volts, have been installed at this point, with lightning arresters on both sides of these coils. The breakdown voltage of these arresters is such that they will not be operated by any rises which it is expected may occur in the potential of the power station ground.

### CONCLUSION

As indicated above, the proper functioning of a power plant and distribution system depends to a considerable extent upon the provision of an adequate communication system by means of which the operating forces can promptly and easily communicate with each other.

In many cases the provision of such a communication system requires the solution of numerous special problems and these are illustrated in this paper by the special problems involved in the design of the communication system of the Conowingo project.

Cooperative consideration by power and telephone engineers of all the available means of communication at an early stage in planning the project, and the adoption of the means most suitable in the specific case should result in the provision of a communication plant of the greatest effectiveness in the operation of the power system.

## Discussion

**E. C. Markley:** It is particularly interesting to note the rather extensive internal communication facilities provided at various points around the building and switch structure. In this connection, is it possible to connect any one of the telephone instruments to the trunk line connected to the Philadelphia load-dispatching system?

As regards dispatching communication, Conowingo is particularly fortunate in its location. It is in an area unusually well provided with underground telephone circuits and therefore only relatively short distances of open-air telephone lines need be protected against storm conditions.

In other parts of the country, an entirely different problem is encountered. Where wire telephony is employed in connection with the operation of 220-kv. and other high-voltage lines, underground cable construction is rather prohibitive and therefore communication must be carried on by open-wire telephone lines. Even in those areas where cable circuits may be used to an extent comparable to this section, hydroelectric stations are usually remote from the centers of the cable telephone system. Power companies have therefore resorted to employing their own telephone lines, carrier current, or space radio. These alternatives were mentioned in the paper, but further discussion along those lines might be of interest, as well as such systems as straight telegraph and printing telegraph systems.

**W. B. Beals:** In regard to the question of the load-dispatcher's circuit being available to communicate with any part of the plant: at the present time the regular load-dispatching circuit is terminated in a telephone, on the station operator's desk, that puts him in direct touch with the load dispatcher's switchboard in Philadelphia. I mentioned a second circuit which has been installed over another route, which is available for what might be called miscellaneous business, general telephone business, or any business that can best be handled by telephone. That line is connected between the regular board of the private-branch exchange—not the load-dispatcher's board—of the Philadelphia Electric Company in Philadelphia and the private-branch exchange at Conowingo. That circuit is available for communication with any of the stations located in various parts of the plant. Furthermore it can be taken over by the load dispatcher and used as an emergency circuit in case of interruption on the regular load-dispatching circuit.

In regard to the telegraph, I think I mentioned that one of the factors that led to the use of telephone facilities was the fact that the Philadelphia Electric Company now has a rather extensive telephone load-dispatching system, and to apply that method of communication to tie-in Conowingo meant simply an extension of the existing system. The printing telegraph, of course, is of very great importance and convenience in case it is desired to keep a record of all orders issued.

**E. B. Tuttle:** In laying out the communication system, this entire interconnection was carefully studied so that any communication circuits which were set up in connection with the Conowingo-Plymouth Meeting part of the system, would be properly coordinated with future possible extensions. That, I think, is one of the particular advantages of making such a communication study very thoroughly in the preparation of the plans for a power system. I should like to add my word to the thought that the power company engineers are fully conversant with their requirements, with what their system needs in the way of power transmission, and also with their needs for communication to a very large extent. Communication engineers, on the other hand, should be in a better position to design what communication facilities are required, particularly if these involve rather extensive interconnection circuits, and so it is particularly fortunate that in connection with this Conowingo job the communication engineers were able at so early a date to assist in the preparation of the system. This is going to be particularly true in the future and even today because of the large increase in the extent of the power system interconnection service. Load dispatching in the East which today may cover 50 miles from a single load dispatcher who would control perhaps all of the system will extend in the course of a few years to hundreds of miles. So it will be of particular advantage to both power and communication companies for communication engineers to be consulted in connection with communication requirements.

The thought was expressed by Mr. Markley that the Conowingo Project was particularly fortunate in its location close to underground communication cables. It may be of interest to note that in setting up the entire project for this intercommunication system about 400 miles of communication circuits appeared to be necessary, and of that not more than 50 miles is in territory where open-wire construction is necessary. The aerial cable as well as the underground cable plant of communication systems are being extended with very great rapidity. During a discussion of this subject with some communication men in Ohio the thought was expressed that the power companies in Ohio did not perhaps feel the necessity for instantaneous communication as did the power companies in Philadelphia, and I could not help expressing the thought that although that might be so at the present time it would not be for long, but that the communication companies might grow in stormproof facilities, about as rapidly as stormproof facilities are demanded. I may be a little optimistic on that subject, however.

In this particular interconnection study, there is one section of 25 miles of open wire required in order to reach the power house, and it is proposed to make that open-wire line of such a strength as will stand any sleet storm recorded to date. The price is not excessive either when constructed on a power line or a communication line.

Mr. Markley expressed an interest in the application of carrier current in connection with load-dispatching systems. The use of carrier current on power lines is a question of economies and continuity of service. Those two points are the prime reasons. It has been pointed out in the papers that when additional emergency service is desired, carrier current may furnish that service. Certain costs in the way of depreciation, interest on the money invested, maintenance, and operation must be taken into consideration, and in the case of the Conowingo-Philadelphia route these amount to very much more than the the annual expense of a leased communication service; and ample facilities were available for emergency routes.

Short-wave radio may also provide, in a similar way, for such continuity of service. At the present time there is extremely little known of the operations of short-wave radio over land for distances under two and three thousand miles. We know, from experiments and studies that have been made, what can be expected of short-wave radio over long distances such as those and for short distances over water, but no experiments of any considerable amount have ever been carried on over land for short distances. We do not know what the effects of electric storms will be, particularly in this part of the country,—and Philadelphia, I believe, is nearly the worst electric storm area we have in the United States. For that reason all you can say for space radio at the present time is that it is experimental. In the course of a few years, additional information will be available and definite recommendations can be made.

Mr. Beals referred to the use of printing telegraph and that brings a very interesting thought to my mind, something on which the communication companies would like to hear some discussion at some time, and that is, what relation does the usage of load-dispatching circuits have to the necessity for printer telegraph or some other recording device. For instance, where the load dispatcher's circuit is assigned exclusively to load-dispatching purposes, as is the case with the Philadelphia Electric Company, there seems to be no desire on the part of the electric company at the present time, at least, for records of the orders passed. Certain other power companies who have their load-dispatching circuits used also for the transmitting of general routine business seem to find it desirable to have a permanent record of all orders passed for load-dispatching purposes. Whether there is any relation between these two facts, I do not know, but I should like to hear some discussion along that line.

**R. A. Hentz:** I can only reiterate what Mr. Beals and Mr. Tuttle have said about the load dispatcher's telephones. The importance of reliable communication is so great that the best was desired—and the cost was not excessive. While we are experimenting with short-wave radio, the results to date have not been reliable enough for this service.

**C. A. Allner:** Referring briefly to the last point mentioned by Mr. Tuttle, both can be suitably combined by hooking up a dictaphone to the telephone as has been the practise on the Pennsylvania-Baltimore System for over ten years.

**E. B. Tuttle:** That has been done in some cases, but engineers who have been working with it find that while certain features are very satisfactory, there are certain other features which are not, due to the load dispatcher's having to change records in the middle of his conversation.

# Quantitative Mechanical Analysis of Power System Transient Disturbances

BY R. C. BERGVALL[1] and P. H. ROBINSON[1]
Associate, A. I. E. E. — Non-Member.

***Synopsis.***—*The quality of service that can be rendered during unavoidable system transients produced by short circuits must be given careful consideration in the analysis of proposed interconnection and transmission projects. An analysis of present systems that have grown until such limitations have apparently been reached, will frequently reveal comparatively inexpensive changes in equipment or operating practise which will permit good service to be given and defer large investments in additional lines for a considerable period.*

*The fundamental mathematical methods for calculating system transients have been presented by other writers during the last few years. These mathematical calculations are of necessity quite involved and consequently can only be applied to very simple power systems. The calculations must be made by thoroughly experienced engineers and the results are not readily understood by the operating staff.*

*In the May 1926 issue of the Electric Journal, under the title "A Mechanical Analogy to the Problem of Transmission Stability," Mr. S. B. Griscom proposed the use of an accurate equivalent mechanical analogy to the electrical system provided perfect springs for representing line reactance could be obtained. A simple mechanical model for qualitatively illustrating the fundamental principles has been demonstrated before various local A. I. E. E. sections and has resulted in a wide general knowledge of the transient behavior of power systems.*

*The present paper covers the adaptation of the mechanical model principles to obtain reasonably accurate quantitative records of transients to be expected on the 220-kv. interconnection between the Philadelphia Electric Co., Pennsylvania Power & Light Co., and the Public Service Electric & Gas Co. These records are obtained by taking motion pictures of the equivalent mechanical system. Resistance or reactance short circuits on transmission lines are duplicated mechanically by applying forces of the proper magnitude and direction to the spring representing the line in trouble, and clearing this spring at each end by blowing fusible links from relays timed to represent the circuit breaker operations on the electrical system. The resulting mechanical oscillations will correspond to those of the electrical system because the inertias, spring characteristics, and torques of the mechanical model elements have been proportioned to the corresponding elements in the electrical system; namely, stored energy, reactance, and kilowatts. The inherent limitation due to imperfect springs has been overcome sufficiently to give results that are accurate within practical limits.*

*It will be shown that the actual setting up of a system on the mechanical model is comparatively simple, and does not require a great deal of experience or mathematical skill. Slow motion pictures of the disturbance can be taken with amateur cameras that are available on the market, and curves of the oscillations plotted from the projection on a screen. The slow motion pictures can be used also for acquainting the operating staff with the effect of various types of disturbances on the system, and for determining the most advantageous sequence of relay operations.*

## FUNDAMENTAL PRINCIPLES OF THE MECHANICAL ANALOGY TO THE ELECTRICAL SYSTEM

THE analogy between the various parts of the electrical system and the equivalent mechanical system are shown in Fig. 1, which represents single generator and its load tied together by the system reactance. The model consists of a generator element and a motor element, mounted on ball bearings and free to rotate independent of each other. For the present, the fault element should be neglected. The rotors have inertia proportional to the stored energy in the generators and loads which they represent. Each element is balanced, and when free from the system and the torque representing generator input or load, is in a state of equilibrium in any position. The weight (a) produces a torque, tending to rotate the generator element in a counterclockwise direction, and the weight (b) produces an equal torque, tending to rotate the motor element in the opposite direction. At synchronous speed, the input kilowatts (torque *a*) to the generator are exactly equal to the output kilowatts (torque *b*) at the load, and the model will be stationary. For any disturbance which suddenly increases the kilowatt load on the system without the governors having time to make a corresponding increase in the generator input, the model will rotate in a clockwise direction, indicating a decrease in frequency. The unbalanced torque (kw. loss in fault) must be absorbed by the inertia of the system and on the mechanical model, will produce oscillations between the relative positions of the two arms similar to the oscillations between the two ends of the electrical system.

With fixed internal voltages in the synchronous machines at the two ends of the system, the phase angle between these voltages plotted against power transmitted is a sine curve similar to Fig. 2 for a purely reactive tie between the ends of the system. The ratio of resistance to reactance of most systems is so small that the resistance may be neglected in making transient analysis without excessive error. The system having power-angle characteristics as in Fig. 2 will pull out of step if the load is gradually increased until the angle between the ends of the system is 90 deg. This is known as the steady-state pull-out limit. When the power being transmitted corresponds to point *a* in Fig. 2, a system disturbance that does not cause the angle to increase beyond point *b* will not cause pull-out.

[1] Both General Engineers, Westinghouse Elec. and Mfg. Co., East Pittsburgh, Pa.

*Presented at the Regional Meeting of District No. 2 of the A. I. E. E., April 17-19, 1928, at Baltimore, Md.*

It is, therefore, possible to have angular swings between the ends of a simple two-element system that considerably exceed 90 deg. without loss of synchronism. It should be noted that a change in the internal voltages of the machines in the electrical system, or a corresponding change in the lengths of the arms on the mechanical system, will modify the power-angle characteristics of the system.

| 8. | Inertia of any element. | 8. | Stored energy at synchronous speed in machines constituting corresponding element of electrical system. |

The first step is to determine the characteristics of the springs which are to represent reactance. The springs should be chosen so that they will not be stretched beyond their elastic limit when the model pulls out. Under this condition, it is desirable to work the springs as close as possible to their elastic limit so that the initial length will be a minimum. Consider that it is desired to select a spring of 10 per cent reactance on a 100,000-kv-a. base. In the electrical system, the 10 per cent on the 100,000-kv-a. reactance tie with 100 per cent voltage at each end, will correspond to a steady-state pull-out limit of

$$\frac{100 \text{ per cent}}{10 \text{ per cent}} \times 100{,}000 = 1{,}000{,}000 \text{ kw.} \qquad (1)$$

The corresponding pull-out torque $T$ of the mechanical model should then be obtained by gradually adding equal weights to the generator and load elements until the steady-state pull-out at 90 deg. between arms is obtained with the spring which is to represent 10 per cent reactance connected to each arm $L$ inches (representing 100 per cent system voltage) from the pivot. This torque $T$ (in ounce-inches) is then equivalent to 1,000,000 kw. on the electrical system.

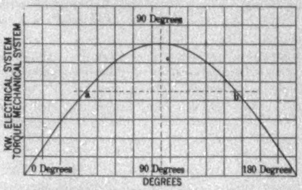

FIG. 2—ANGLE BETWEEN $E_r$ AND $E_s$ IN ELECTRICAL SYSTEM ANGLE BETWEEN GENERATOR AND MOTOR ARMS IN MECHANICAL SYSTEM

The springs representing the reactances of the other parts of the system are then proportioned, taking the above spring as a base. Under the pull-out condition, the force in the spring is $\frac{1.41\ T}{L}$ ounces. This force elongates the 10 per cent reactance spring to 1.41 $L$ in., or would elongate a 1 per cent reactance spring to 0.141 $L$ in. A one per cent reactance spring then can be determined by the fact that it assumes a length of $0.141\ L \div \frac{1.41\ T}{L} = \frac{L^2}{10\ T}$ in. when a weight of one ounce is hung on it. Now the springs to represent the various reactances of a system can be cut to proper length by hanging on them a one-ounce weight,

FIG. 3—(SEE FIG. 1 FOR SET-UP ON MECHANICAL MODEL)

(or a fraction thereof, if it is found necessary to use a lesser weight). For example, a five per cent spring should reach a length five times that of the one per cent spring with the same weight applied.

The errors due to springs having a finite initial length can be eliminated through the working zone by winding the springs so that there will be an initial compression between turns. As shown in Fig. 4, the relation between spring length and force is then a straight line beyond the finite length of the spring and if projected, this line would start from zero. In the actual operation of the model, the springs are generally stretched beyond the initial length and therefore have such characteristic that no appreciable error is introduced.

The stored energy in a synchronous machine =

$$E = \frac{2.3\,(W\,R^2)\,(\text{rev. per min.})^2}{10^7} \text{ kw.-seconds at synchronous speed.}$$

($W\,R^2$ is in pounds-feet squared) (2)

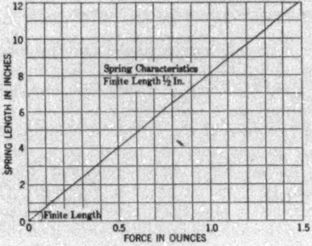

Fig. 4

The total stored energy $E$ at synchronous speed in the machines constituting any particular element of the system may be converted into inertia of the corresponding mechanical model elment as follows:

$$W_1\,r_1^2 = \frac{E \times T \times 2.05}{10^6} \text{ ounce-inches squared.}$$

$E$ = Stored energy in synchronous machines in kw. seconds.

$T$ = Ounce-inches of torque on model at steady-state pull-out with 10 per cent reactance spring attached to each arm $L$ inches (equals 100 per cent voltage) from pivot. (3)

After determining the spring constant and the inertia in the foregoing manner, it can readily be shown that the natural period of any given element of the electrical system and the corresponding element of the mechanical system are identical. Consider the case of a generator having $E$ kw. seconds of stored energy at synchronous speed connected to a system of infinite capacity through 10 per cent reactance on a 100,000-kv-a. base. With 100 per cent internal voltage in the generator, the pull-out of this system will be 1,000,000 kw., as previously shown. The kw. required to produce one electrical degree of displacement when the system is carrying enough load to have a 45-deg. angle then will be

$$p_1 = \frac{1{,}000{,}000 \cos 45}{57.3} = 12{,}300 \text{ kw. per electrical degree.} \quad (4)$$

The natural period of the electrical system at this point then is

$$P = 148.6 \sqrt{\frac{E}{p_1 \times f \times 10^5}} \text{ seconds} \quad (5)$$

$f$ = 60 cycles

Substituting values for $p_1$ and $f$ in (5)

$$P = 148.6 \sqrt{\frac{E}{12{,}300 \times 60 \times 10^5}} \quad (6)$$

$$P = 54.3 \times 10^{-5} \sqrt{E} \text{ seconds} \quad (7)$$

In the equivalent mechanical system the torque at pull-out equals $T$ ounce-inches. The torque per mechanical degree of displacement from the 45-deg. position will be

$$T_1 = \frac{T \cos 45 \text{ deg.}}{57.3} = 0.01234\,T \text{ oz.-in. per deg.} \quad (8)$$

The natural period of the equivalent mechanical system from the torsional pendulum formula is then

$$P = 0.0422 \sqrt{\frac{W_1\ r_1^2}{T_1}} \text{ seconds} \quad (9)$$

Substituting for $W_1\,r_1^2$ its value from equation (3) and for $T_1$ its value from (8)

$$P = 0.0422 \sqrt{\frac{E \times T \times 2.05}{10^6 \times 0.01234\,T}} \quad (10)$$

$$= 54.3 \text{ by } 10^{-5}\,E \text{ seconds} \quad (11)$$

From a comparison of (7) and (11), the natural period of the equivalent mechanical system is identical with that of the electrical system.

The above discussion applies directly to all conditions imposing symmetrical loads on the different phases. For fault conditions, the electrical load may be unsymmetrical; *e. g.*, the fault usually is from one-phase wire to ground. From the stability standpoint, however, a single-phase fault on a polyphase system may be represented accurately by an equivalent symmetrical shunt impedance across the three phases at the point of fault. This was demonstrated by Messrs. Evans and Wagner in their paper *Studies of Transmission Stability*, Appendix III, presented at the Midwinter Convention of the A. I. E. E. Feb. 8-11, 1926.

## COMPARISON OF CALCULATED VS. MECHANICAL MODEL TEST RESULTS ON TWO-ELEMENT SYSTEM

Fig. 3-A shows two generating stations, each supplying some local load and tied together by two transmission lines. Station *G* has a total of 400,000 kw. in waterwheel generators on the line supplying a local load of 130,000 kw. and transmitting 240,000 kw. towards station *R*. Station *R* has 500,000 kw. in the steam turbines on the line carrying a load of 360,000 kw. The remaining 240,000 kw. of the local load being obtained over the transmission system. The stored energy of the synchronous machinery at station *G*, calculated for each item of equipment in accordance with formula (**2**) total 13.5 by $10^5$ kw. seconds. Likewise at station *R* the total is 68 by $10^5$ kw. seconds.

In setting up a complicated system the number of elements must necessarily be kept down to a minimum in order to reduce the possibility of interference between springs. It is desirable, therefore, to combine the inertia of the local load with that of the local generating station into a single element on the mechanical model. Except for the phase angle which it produces in the generator, the local load has no effect on the over-all phase angles of the system. The simplified system used in setting up the mechanical model and calculating the curves which follow is shown in Fig. 3-B. By combining the load with the generator element, the system has been simplified to only two elements on the mechanical model. Disturbances on such a comparatively simple system can readily be calculated by a point-by-point method for comparison with the test results from the mechanical model.

In setting up the mechanical model, the various springs were proportioned to the reactances of the sections they represent, in accordance with the methods previously outlined. The torque equivalent to the 240,000-kw. load being transmitted was applied to the generator and motor elements tending to turn them in opposite directions, thereby holding the system in equilibrium. The inertia of each element of the mechanical model was proportioned to the stored energy of the corresponding element of the electrical system in accordance with (**3**), thereby making the natural period of the mechanical system identical with that of the electrical system.

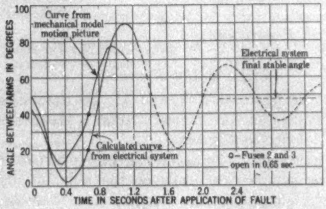

Fig. 5—Comparison of Calculated and Test Curves

For 290,000-kw. line to ground fault on the system shown by Fig. 3A

Fig. 1 shows the mechanical model set-up of the above system. The fault has been assumed to be single-phase line-to-ground, with 39 ohms resistance in the ground circuit. Based on the internal voltages in the machine being practically maintained by means of quick response excitation, the loss in the fault amounts to about 290,000 kw. This is based on internal machine voltages being somewhat higher than the actual transmission voltage, and these higher voltages were also used on the arms of the mechanical model. The power in the fault was converted into equivalent ounce-inches of torque on the mechanical model, and this torque was suddenly applied to the transmission line on which the fault occurred by means of a very light rotating "fault arm" mounted on a ball bearing as shown in Fig. 1. Here the two ends of the spring representing the line in trouble are tied into the remainder of the system through fusible links which represent the circuit breakers at each end of line 2-3 (Fig. 3-B). The *C V* relays are timed to blow these fuses in the same sequence as the circuit breakers would clear the fault on the actual system. It is not necessary to blow the fuses simultaneously. For example, if fuse No. 2 is blown first, the fault arm immediately swings clockwise and continues to apply the fault through fuse No. 3 and the section of spring representing the reactance of this section of the line. The fuses are blown through insulating transformers so that the current can be kept out of the springs. When fuse No. 3 blows, the fault is entirely removed from the system and the fault arm swings clear with spring 2-3 attached to it, thus removing the unbalanced torque which tends to rotate the model, and indicating a decrease in system frequency. If the disturbance is not sufficiently severe to cause pull-out, the system will oscillate and finally assume a new stable angle corresponding to that when transmitting 240,000 kw., with only one line in service.

Fig. 6—Extracts from Motion Pictures of 290,000-Kw. Fault on System by Figs. 1 and 3

a. Mount after fuse No. 1 (Fig. 1) is blown, releasing fault arm.

b. 0.25 sec. after fault. Note the decrease in angle.

c. 0.60 sec. after fault. Fuses No. 2 and 3 (Fig. 1) beginning to clear the spring which is attached to the fault arm.

d. 0.75 sec. after fault. Fault arm with spring 2-3 attached to it, has been cleared from the system.

For curves plotted from the motion picture record, see Fig. 5

By referring to the schematic diagram in Fig. 1, it can be seen that the fault is applied by releasing the weight attached to the fault arm through the blowing of fuse No. 1 immediately after the pushbutton is closed. The closing of this pushbutton also starts the *C V* relays so as to blow fuses No. 2 and No. 3 in the proper sequence.

The weight was attached to the fault arm through a long rubber band, so that no time would be lost in accelerating the mass of the weight applied to the fault arm. The radius of the hub of the fault arm is so small that the rubber band will have linear characteristics, even with a considerable change in the angle of the fault arm.

In some cases where the fault resistance is low, the positive sequence voltage, which is the voltage represented on the model, will dip to about 67 per cent of normal at the point of fault. In such cases an additional spring was used at the top of the fault arm and released simultaneously with the fault arm, so that the positive sequence voltage would be pulled down to this value.

Fig. 6 shows extracts from the motion picture film of the mechanical model with the equivalent of a 290,000-kw. line-to-ground fault applied to the system shown in Fig. 3-A.

Fig. 5 shows the angle between the generator and motor internal voltages at each instant from the time that the fault is applied. The curve taken from the motion picture of the mechanical model is plotted for comparison with the curve calculated from the electrical quantities of the system by a point by point method. There is a fairly close coincidence between the curves, particularly at the extreme angular over travel after the breaker opened. The mechanical model curve has a certain amount of damping, whereas the solid portion of the calculated curve has no allowance for damping which would actually be present on the electrical system. This particular disturbance shows the mechanical model in the least favorable light, since the high kw. loss in the fault is accompanied by only a small reduction in the positive sequence voltage and causes the comparatively light generator arm to swing toward the motor arm so that the finite length of the spring came into action. The finite length of spring coupled with no allowance for damping in the calculation of the electrical system is responsible for the difference between the minimum values of angle in the two curves.

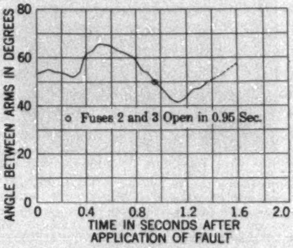

FIG. 7—140,000-KW.—10 OHM LINE TO GROUND FAULT ON THE SYSTEM SHOWN BY FIG. 3A

The fault load must be supplied from the stored energy in the synchronous equipment on the system, causing a decrease in speed, because the disturbance is over in such a short time that ordinary governors cannot come into play. It should be noted that the synchronous equipment at *G* has considerably less stored energy than that at R. Because of the lesser stored energy at *G*, the torque of the fault tends to slow the generator down faster than the load end of the system *R*; therefore for the first four-tenths of a second, there is actually a decrease in the angle. Both breakers (fuses) were assumed to clear simultaneously in 0.65 sec. This is exactly simulated on the mechanical system by blowing the fusible links No. 2 and No. 3 in 0.65 sec. It should be noted that the breaker cleared at a point where the angle was considerably less than the final stable angle, with one section of line out so that considerable over-shooting resulted. The dotted section of the calculated curve shows an assumed decrement leading toward the final stable angle. It should be noted also that when the fault was first applied, a slight discrepancy existed between the calculated electrical angle and the actual angle on the mechanical model.

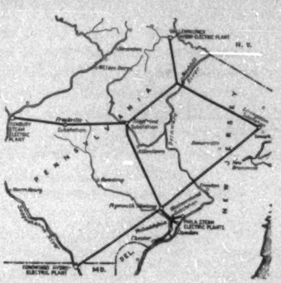

FIG. 8—TERRITORY IN PENNSYLVANIA AND NEW JERSEY TO BE SERVED BY 220-KV. INTERCONNECTED LINES

Fig. 7 represents the 10-ohm low-resistance fault on the system shown by Fig. 3-A, with about 140,000 kw. dissipated in the ground circuit. The positive sequence voltage at point of fault was depressed by means of an auxiliary spring, as previously described, to about 73 per cent of normal at the instant the fault was applied. This depression of the position sequence voltage weakened the tie between the two elements so that the angular displacement between the two actually increased during the first part of the fault, which contrasts with Fig. 5 where the positive sequence voltage was fairly well maintained on account of the high resistance in the fault. The circuit breakers (fuses) cleared the line in trouble at both ends in 0.95 seconds. At this time, the arms were traveling toward each other, and there was some overshooting down to the minimum angle occurring at 1.13 sec. before the arms started traveling apart toward their new positions, with one line out of service.

## Mechanical Model Set-Up of Interconnected System

Fig. 9 shows the 220-kv. interconnection between the Philadelphia Electric Co., Pennsylvania Power & Light Co., and the Public Service Electric & Gas Co. reduced to a simple form for setting up on the mechanical model in the same manner as Fig. 3-B was obtained from Fig. 3-A. This figure shows one of the probable future load conditions. The loads supplied local to each generating station are not shown, as they produce very little effect on the phase angular relations of the interconnected system. Only the transmitted power is shown. As previously outlined, the stored energy and reactance of all of the connected generators were included even though under normal conditions these generators may contribute a slight amount of power to the interconnection. During transient disturbances their stored energy and reactance comes into effect and must be considered.

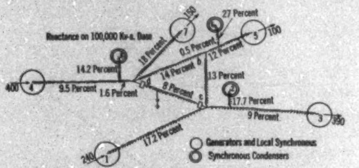

FIG. 9—ARROWS INDICATE THOUSANDS OF KW. ENTERING AND LEAVING NETWORK

Stored Energy of Each Element in Kw-Sec.

1. Conowingo 7.56 × $10^5$
2. Plymouth Meeting 2.2 × $10^5$
3. Phil. Elec. Co., 32.5 × $10^5$
4. P. P. & L. Sunbury 78.0 × $10^5$
5. Public Service Co. 91.0 × $10^5$
6. Livingstone 1.5 × $10^5$
7. Frackville & Siegfried 66 kv. load 39 × $10^5$
8. Siegfried & Frackville Condensers 4.1 × $10^5$

Springs were chosen to represent properly the reactance of each element of the system. The torque required to represent the power generated or the power taken out of the system at each element was determined, and the proper weight to be suspended from each element calculated. In attaching the springs to the arm, allowances were made for the calculated internal voltages. The inertias of the various elements were properly proportioned by hanging equal masses across the elements that required additional inertia. For convenience, these masses were made of tubes that could be loaded with shot. Figs. 10 and 11 show the Fig. 9 system as actually set up on the mechanical model.

With the load and springs properly proportioned, the phase angles between the various component parts of the system assume their proper relationships automatically. The phase angles shown in Fig. 11 correspond very closely to the calculated values. For the set-up shown, the load conditions were such that practically no power was being transmitted over the section of the triangle *B-C* in Fig. 9. Fig. 10 shows this to be true. It can readily be seen that a fault on line *A-C* will be the most severe condition, since the power must be transmitted over the single lines *A-B* and *B-C* after the faulty section *A-C* is tripped out.

Some lines in Fig. 10 utilize two springs in parallel because a single spring of the proper characteristics was not available.

## Analysis of Fault on Line *A-B* Fig. 9 from Motion Picture Record of Equivalent Mechanical Model

*Condition No. 1.* A line-to-ground short circuit on line *A-C* near end *A* having resistance equal to the reactance to the point of fault was considered. This gave the maximum possible kw. loss in the fault and amounted to about 450,000 kw. for the system shown. (For a complete discussion of the effect of variable ground resistance refer to an article by Mr. S. B. Griscom entitled "Characteristics of Ground Faults on Three-Phase Systems" in the April 1927 issue of the *Electric Journal.* The torque representing this kw. loss in the fault was applied to the spring by means of the very light rotating fault arm shown in Fig. 13a. The function of this arm can be seen more readily from Fig. 1. The spring representing line *A-C* was attached to the remainder of the system by means of fusible

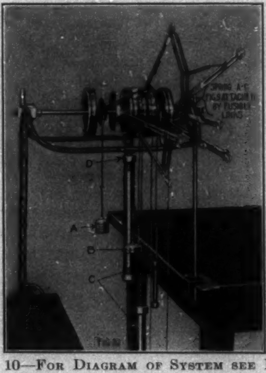

FIG. 10—FOR DIAGRAM OF SYSTEM SEE FIG. 9

A. Weight producing torque tending to rotate element (1) counter-clockwise, representing 120,000 kw. generated.

B. Weight producing torque tending to rotate element (3) clockwise, representing 195,000 kw. load. This weight is at greater radius than (A) accounting for the smaller weight

C. Tubes of equal mass suspended over element (4) to increase its inertia from 32.5 (element alone) to 78 as required by tabulation on Fig. 9

D. Load weights (partly obscured) representing 200,000 kw. being generated by station (4) links arranged to be blown by *C V* relays in order to duplicate the actual opening of the circuit breakers on the system. Fig. 13a shows two successive results at the instant of the application of the fault. The camera shutter did not happen to be open when fuse No. 1 blew, releasing the fault arm, and a spot was placed on the first picture to indicate the blowing of the fuse. The rapid movement of the torque arm is evident, since the pictures are only 0.05 sec. apart.

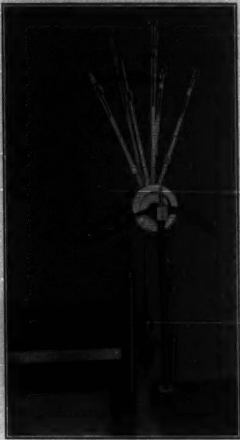

Fig. 11—Front View of Fig. 10

Curve (*d*), Fig. 12, shows the complete angular variation between stations No. 3 and No. 4 and curve (*e*), Fig. 12, shows the corresponding variation between stations No. 1 and No. 3. A cycle counter was included in the field of vision of the motion picture camera as a check on the speed of the film. In Condition No. 1 breakers *A* and *C* cleared the line simultaneously as indicated in Fig. 12. The two successive exposures in Fig. 13b show the released fault arm with the spring *A-C* attached to it swinging clear of the system. In this case the camera shutter did not happen to be open when the fuses representing *A* and *C* cleared.

Fig. 13c shows the crest of the maximum angle between elements 3 and 4. The torque arm with spring *A-B* attached is shown against the stop.

After reaching the maximum angular separation shown in Fig. 12, the stations will oscillate and gradually settle at the new stable position with one line out of service. The present mechanical model does not permit complete rotation and these final oscillations could not be obtained; but they are of no great importance. Fig. 13d shows the final steady-state operating condition with line *A-C* out of service. A considerable increase in the angle between 3 and 4 is evident by comparison with Fig. 13a.

*Condition No. 2.* The magnitude and location of the fault is identical with Condition No. 1, the only change from Condition No. 1 being in the time of operation of the circuit breakers. By referring to Fig. 12, breaker *A* cleared in 0.68 sec. and breaker *C* in 0.93 sec. When breaker *A* opened, the power taken by the fault had to be transmitted over line *A-B* and *B-C* thereby producing a more rapid increase in the angle between the extreme ends of the system shown by Fig. 12. Fig. 14a shows the conditions at the instant fuse No. 1 cleared, releasing the fault arm. The camera shutter happened to be open when this occurred and the flash can be seen in the picture.

Fig. 14b shows the opening of circuit breaker *A* about 0.68 sec. after the torque arm was released. A dot has been placed on the film to represent the flash of the fuse blowing. The location was obtained from a high-speed film taken simultaneously.

Fig. 14c shows the instant that fuse *C* cleared, allowing the torque arm to swing clear of the system with the spring *A-C* attached to it. The flash has been indicated by a dot located from the high-speed film.

Fig. 14d shows the angular swing due to over-travel after the breaker *C* is cleared. The crest of this swing could not be obtained before element 3 hit the stop, but by comparison with a power-angle curve between stations No. 4 and No. 3 constructed in a manner similar to Fig. 2, it can be ascertained that the system would remain in synchronism. The final steady-state condition with line *A-C* out of service will be the same as Fig. 13d. As indicated by the mechanical model, the effect of opening breaker *C* after breaker *A* is somewhat more severe than will actually be experienced in service, because the reactance to the point of fault is

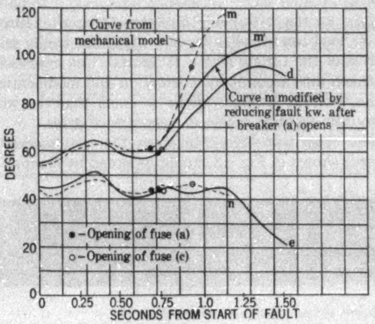

Fig. 12—Condition No. 1

*d* = angle between 3 and 4 (Fig. 9)
*e* = angle between 1 and 3 (Fig. 9)

Condition No. 2

*m* = angle between 3 and 4 (Fig. 9)
*n* = angle between 1 and 3 (Fig. 9)

increased after breaker *A* opens and a corresponding reduction in the kilowatt loss in the fault should have been made. This reduction can readily be calculated and the slope of curve (*m*) Fig. 12 modified by calculation. It would also be possible to arrange to release some of the torque when breaker *A* clears, but this complication can hardly be justified, since the result can be modified readily by calculation. The error due to the torque arm having to swing over sufficiently to take up the initial length of the spring after fuse *A* clears has been found to be very slight due to the small inertia of the torque arm. If desired, this may easily be taken into account by calculation and modifications made, but the change will be so small that the work cannot be justified except in very special cases.

Fig. 13—Condition No. 1
Extracts from Motion Pictures of 450,000-Kw. Fault on System Shown by Fig. 9

a. Conditions at start of fault
b. Fuses (a) and (c) clear practically at the same time
c. Maximum angular swing between 3 and 4
d. Steady state operating condition with line a-c. out of service
For curves plotted from the motion picture record, see Fig. 12

The close coincidence between the two successive records shown in Fig. 12 should be noted by comparing the curves for conditions No. 1 and No. 2 prior to the opening of the fuses.

Fig. 14—Condition No. 2
Extracts from Motion Pictures of 450,000 Kw. Faults on System Shown by Fig. 9

a. Fault applied
b. Fuse (a) opens
c. Fuse (c) opens
d. Maximum angle between 3-4 before element 3 hit the stop
For curves plotted from the motion picture record, see Fig. 12

During the foregoing tests, the application of the force representing the short circuit is made at such an angle that the positive sequence voltage at the point of fault was represented by corresponding depression in the spring. The resistance at the point of fault was equal to the reactance in order to obtain the maximum kw. loss in the fault and this resistance limited the current to such a value that a comparatively small reduction in the positive sequence voltage resulted.

*Condition No. 3.* This condition represents a line-to-ground fault on line *A-C* (Fig. 9) near (*A*) with zero resistance in the fault. The positive sequence voltage at the point of fault will be reduced to about 67 per cent of normal. This was represented by attaching a spring near the end (*A*) which could be released by the blowing of a fusible link to depress the springs representing line reactance to correspond to 67 per cent voltage without applying any torque (kw.) to the system. For convenience, this spring was attached to the fault arm.

Fig. 15 shows the angular change between the extreme ends of the system plotted against time as taken from the motion picture record. Fig. 16a shows the initial condition a moment after the voltage at (*A*) was depressed to about 67 per cent of normal. Fig. 16b shows conditions at the instant the fusible link representing breaker *C*, cleared. The fuse representing breaker *A* failed to clear and Fig. 16c shows the angular relation existing when stations No. 3 and No. 4 were at their extreme angular displacement. With the internal voltages in the generators maintained, the system will not pull out of step even though breaker *A* fails to clear the fault. This may be ascertained from Fig. 15 since the maximum angle of 140 deg. between stations No. 3 and No. 4 did not cause pull-out, and they are swinging back toward a smaller angle. The advantage gained by the use of high-speed excitation, which in so far as practical, maintains the internal voltage in the generators, is evident from an inspection of Fig. 16c.

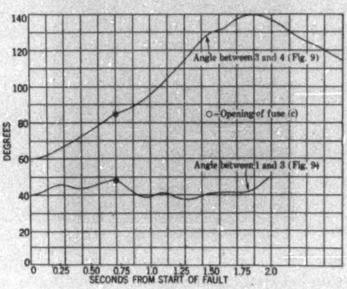

Fig. 15—Condition No. 3—Zero Resistance Line to Neutral Fault Near (a) Fig. 9

## CONCLUSION

This paper describes the initial attempt to make a quantitative analysis of system transients from motion picture records of a mechanical system having constants proportioned to those of the electrical system. The model was built up of existing equipment and proved to be adequate for the solution of a system problem that involved too many elements for handling by means of mathematical calculation. The experience gained with this model will prove of value in the development of a model having a greater degree of flexibility for use in analyzing transient conditions on systems with accuracy limitations comparable with the resistance type calculating board now generally used to determine short-circuit conditions for relay and circuit-breaker applications.

It is possible to add a great many refinements to the mechanical model to represent the reactions taking place on systems during transients which have not been taken into account on the device that has been described. In the authors' opinion, it is preferable to use a simple device because results obtained will be comparable in accuracy with the estimates of system conditions to be investigated, since these estimates generally are concerned with conditions that have been projected considerably into the future. Methods of representing a decrease in the internal voltages of the machines and taking into account line resistance as well as reactance have already been described in the May 1926 issue of the *Electric Journal*.

FIG. 16—CONDITION NO. 3

EXTRACTS FROM MOTION PICTURES OF ZERO RESISTANCE LINE TO NEUTRAL FAULT AT (a) FIG. 9

a. Instant after fault was released, depressing the voltage at (a) to about 66 per cent normal

b. Instant after fuse (c) opened

c. Maximum angular swing between 3 and 4

In the transient conditions analyzed in this paper, the load and the kilowatts of input to the generators were assumed to remain constant during the disturbance. Line-to-neutral short circuits seldom cause the positive sequence voltage to drop below 70 per cent of normal and most induction and synchronous motor loads will stay on the line. The transient is over in such a short time that the governors of the generating units do not have time to change greatly the power input. If, however, it is desired to change these factors, it is readily possible by either electrical or mechanical means to change the torque applied to the various elements during the transient. It is also possible to change the torque representing the kilowatts in the fault at the same time that circuit breakers open and reduce the fault current.

The mechanical analogy can be used for the following purposes:

1. Investigation of the adequacy of proposed transmission systems and interconnections for rendering good commercial service in spite of the transient disturbances that are to be expected.

2. Determination of the characteristics that are to be desired in equipment in order to render the required service.

3. Analysis of the most desirable sequence of relay operation. This factor is of great importance in the successful operation of large transmission systems.

4. The mechanical model should be of value in analyzing disturbances on existing systems that have been recorded with automatic oscillographic instruments. The disturbances as recorded can be repeated on the mechanical system set-up and the transients studied by means of slow motion pictures for the benefit of the operating staff.

The results obtained with the initial mechanical model used for quantitative analysis of system disturbances indicate the possibility of building somewhat more flexible mechanical models and the preparation of simple instructions for setting up systems so that the work can be handled by men who have had no previous experience in the calculation of system transients. The mechanical model can be used for quickly analyzing transients on systems having too many elements to be handled mathematically.

In the development of the mechanical model for quantitatively analyzing system transients, the authors have freely consulted the past work of Messrs. Griscom, Wagner, Evans, and Fortescue. The authors wish to express their appreciation of the energetic assistance with the mechanical work rendered by Mr. R. W. MacKay.

### LIST OF SYMBOLS USED IN THE FORMULAS

$L$ = Length of arm on mechanical model representing 100 per cent voltage.

$T$ = Ounce-inches of torque required to pull out the system with a 10 per cent reactance spring attached to each arm at $L$ inches from the pivot. It is equivalent to the calculated pull-out kilowatts of the identical electrical system.

$W_1 r_1^2$ = Inertia of mechanical model element in ounce-inches squared. $W_1$ is weight of element and arm in ounces (not mass) and $r_1$ is radius of gyration in inches.

$E$ = Stored energy at synchronous speed in the machines at a station measured in kw-sec.

$W R^2$ = Inertia of a synchronous machine rotor in pounds-feet squared. $W$ is the weight of rotor in pounds (not mass) and $R$ is radius of gyration in feet.

Rev.per min. = Revolutions per minute.

$p_1$ = kw. per electrical degree of displacement from normal position.

$P$ = Natural period of electrical or mechanical system in seconds.

$f$ = Frequency in cycles per second.

$T_1$ = Torque in ounce-inches per mechanical degree of displacement from the normal position.

## Appendix

### Derivation of Formulas

*Formula* (**1**). Consider a system having 100 per cent internal voltage maintained at each end and a total reactance of $X$ per cent based on $M$ kv-a. Then:

$$\frac{100 \text{ per cent}}{X \text{ per cent}} M = \text{kw. at pull-out.} \qquad (\mathbf{12})$$

It is well known that pull-out will occur at a 90-deg. angle between the voltages with a pure reactance tie. The reactive line drop then equals 100 per cent $\sqrt{2}$, which corresponds to $\frac{100 \text{ per cent } \sqrt{2}}{X \text{ per cent}} M$ kv-a. being transmitted. Since the phase angle is 45 deg. the kw. at pull-out as given by (**12**) may be obtained by multiplying the kv-a. by cos 45 deg. $= \frac{1}{\sqrt{2}}$.

*Formula* (**2**). This formula has been published by others without any derivation being given. For convenience, it will be derived below.

The standard formula for rotational kinetic energy is:

$$\frac{W\ R^2\ \omega^2}{64.4} \text{ ft.-lb.}$$

($W$ is weight of rotor in pounds)
($R$ is radius of gyration in feet)
($\omega$ is angular velocity in radians per second). (**13**)

Substitute in (**13**) for $\omega$ its value in terms of (rev. per min.):

$$\omega = 2\,\pi \frac{(\text{rev. per min.})}{60} = \frac{\pi\ (\text{rev. per min.})}{30}$$

radians per second. (**14**)

Multiplying by the factor 13,560 $\times 10^{-7}$ to convert ft.-lb. to kw. Second formula (**2**) is obtained.

$$(\mathbf{2})\quad \text{E} = \frac{2.3\ (W\ R^2)\ (\text{rev. per min.})^2}{10^7} \text{ kw-sec.}$$

*Formula* (**3**). Conversion of electrical system stored energy ($E$-kw-sec.) into equivalent $W_1 r_1^2$ (ounce-inches squared) on the mechanical model.

In the paper under "Conversion of the Electrical System into Equivalent Mechanical System" the method of obtaining the proportionality factor between kilowatts in the electrical system and torque in ounce-inches on the mechanical model was described. Consider an element of the electrical system having $E$ kw.-sec. of stored energy at synchronous speed. If a load $\text{kw.}_{po} = T$ oz.-in. on the mechanical model ($\text{kw.}_{po}$ = pull-out kw.) is taken from the synchronous machines constituting $E$, they will slow down a total of $\phi_1$ electrical degrees if no additional power is supplied.

$$\phi_1 = \frac{5400\ (\text{kw.}_{po})}{E}\ t_1^2 \text{ elec. deg.} \qquad (\mathbf{15})$$

This formula will be derived later in the appendix.

The torque $T$ applied to the mechanical system should cause a movement of $\phi_1$ mechanical degrees in $t_1$ seconds if the $W_1 r_1^2$ of the model is properly proportioned to $E$ of the electrical system. For the mechanical system:

$$\phi_1 = \frac{11{,}085\ T}{W_1\, r_1^2}\ t_1^2 \text{ mechanical degrees.} \qquad (\mathbf{16})$$

This formula will be derived later in the appendix.

Equating (**15**) and (**16**) and canceling out $t_1^2$:

$$W_1\, r_1^2 = \frac{E \times T \times 2.05}{\text{kw.}_{po}} \text{ oz.-in. squared.} \qquad (\mathbf{17})$$

In the example shown in the paper $\text{kw.}_{po} = 10^6$ or

$$(\mathbf{3})\quad W_1\, r_1^2 = \frac{E \times T \times 2.05}{10^6} \text{ oz.-in. squared.}$$

In the foregoing, $E$ has been assumed to remain constant during changes of speed. This has been found to be sufficiently accurate for stability calculations because the transients last such a short time that the departure from synchronous speed is very small.

*Formula* (**15**). Used in deriving formula (**3**).

The torque ($T_{36}$ lb.-ft.) that will change the angular velocity of a body having an inertia of $W\,R^2$ (lb.-ft. squared) from $\omega_1$ to $\omega_2$ radians per second in time $t$ seconds as given by the standard formula is:

$$T_{36} = \frac{W\ R^2\ (\omega_1 - \omega_2)}{32.2\, t} \text{ lb.-ft.} \qquad (\mathbf{18})$$

In deriving formula (**16**) it is convenient to consider all machines as running at 3600 rev. per min. and convert the $W\,R^2$ and electrical torque to this base, since the mechanical and electrical degrees are the same at this speed. From formula (**2**).

$$E = \frac{2.3\ (W\ R^2)_{36} \times 3600^2}{10^7} \text{ kw.-sec.} \qquad (\mathbf{19})$$

or $(W\ R^2) = 0.335\ E$ lb.-ft. squared at 3600 rev. per min. to have stored energy of $E$ kw.-sec. (**20**)

The torque ($T_{36}$ ft.-lb.) at 3600 rev. per min. produced by ($\text{kw.}_{po}$) is:

$$\frac{\text{kw.}_{po}}{0.746} = \frac{2 \times 3600 \times T_{36}}{33000} \qquad (\mathbf{21})$$

or

$$T_{36} = 1.95\ \ (\text{kw.}_{po}) \text{ lb.-ft.} \qquad (\mathbf{22})$$

The angular velocities $\omega_1$ and $\omega_2$ in radians per second may be converted to degrees per second as follows:

$$\omega_1 = \frac{\omega_{10}}{57.3} \quad (\mathbf{23}) \qquad \omega_2 = \frac{\omega_{20}}{57.3} \quad (\mathbf{24})$$

$\omega_{10}$ and $\omega_{20}$ are in either electrical degrees per second or mechanical degrees per second on the 3600 rev. per min. base previously referred to.

Substituting (**20**), (**22**), (**23**), and (**24**) in formula (**18**):

$$(\text{kw.}_{pe}) = \frac{E\,(\omega_{10} - \omega_{20})}{10{,}800\,t} \qquad \textbf{(25)}$$

The angular change $\phi_1$ (elec. deg.) in time $t_1$, may be determined as follows:

$$\phi_1 = \int_0^{t_1} (\omega_{10} - \omega_{20})\,dt = \int_0^{t_1} \frac{10{,}800\,(\text{kw.}_{pe})}{E}\,t\,dt \qquad \textbf{(26)}$$

or $$\phi_1 = \frac{5400\,(\text{kw.}_{pe})\,t_1^2}{E}\ \text{elec. deg.} \qquad \textbf{(15)}$$

*Formula* (**16**). Used in deriving formula (**3**). Starting from formula (**18**) as a basis substitute for $T_{36}$ (ft.-lbs.) its equivalent torque $T$ (in.-oz.)

$$T_{36} = \frac{T}{16 \times 12} = \frac{T}{192} \qquad \textbf{(27)}$$

The $W R^2$ (lb.-ft. squared) may be converted into $W_1 r_1^2$ (oz.-in. squared) as follows:

$$W R^2 = \frac{W_1 r_1^2}{16 \times 12 \times 12} = \frac{W_1\ r_1^2}{2304} \qquad \textbf{(28)}$$

Substituting (**23**), (**24**), (**27**), and (**28**) in formula (**18**):

$$T = \frac{W_1 r_1^2\,(\omega_{10} - \omega_{20})}{22{,}170\,t}\ \text{oz.-in.} \qquad \textbf{(28)}$$

($\omega_{10}$ and $\omega_{20}$ in mech. deg.)

The angular change, $\phi_1$ (deg.) in time $t_1$ may be determined as follows:

$$\phi_1 = \int_0^{t_1} (\omega_{30} - \omega_{20})\,dt = \int_0^{t_1} \frac{22{,}170\ T}{W_1 r_1^2}\,dt \qquad \textbf{(29)}$$

or $$\phi_1 = \frac{11{,}085\ T}{W_1 r_1^2}\,t_1^2\ \text{mech. deg.} \qquad \textbf{(16)}$$

## Discussion

**B. Van Ness:** The eastern 220-kv. interconnection presents an unusually interesting problem from the stability standpoint because of the large number of different factors involved. Of particular interest is the proposed parallel operation of existing stations equipped with normal excitation and new stations equipped with quick response and even superexcitation.

In this connection I should like to ask the authors of the papers if their studies have indicated any need for the installation of quick-response excitation in the existing stations in order that the speed of response be more nearly uniform throughout the system; also if voltage fluctuations and surges are to be expected from wattless readjustment caused by the difference in speeds of excitation response.

**L. G. Smith:** There are several points that I am not sure the authors of the paper have considered in designing the mechanism for calculating system stability. One is the effect of steam generating stations in that the steam governors may start to function during the period of oscillation during the transient condition and thus superimpose their effect upon the natural oscillation that may occur. Another point is the time lag of relays which may have some effect upon system stability. The energy supplied to the normal short circuit is almost entirely wattless. Under these conditions we might actually have an unloading effect on the generators and a tendency for them to speed up. This may have some effect upon the stability of the system. Can this effect be determined?

The growth of interconnections has introduced the subject of stability in many of our power systems. In the East it is more or less a practise to interconnect systems through solid interconnections, attempting to hold all parts of the system in synchronism. I understand that there is a tendency on the Pacific Coast to adopt a system of loose linkages, that is, to tie the system together loosely so that various parts will separate in case of trouble. Perhaps Mr. Baum can give some thoughts on this subject.

Quick response excitation would function to hold the voltage up during a short circuit. Suppose that the trouble is cleared and the short circuit removed from the system after the quick-response excitation of the condensers has functioned. Is the system designed to reduce the voltage quickly in order to prevent an over-voltage on the synchronous condensers, which may cause an insulation failure on some part of the system?

**F. G. Baum:** No electrical system can be operated without means for removing defective sections. The solution has been the bother of the electrical engineer for many years.

Thirty years ago generators were often advertised as being very good because they had very large reactance. One manufacturer made it a point that you could actually short circuit his machine for hours at full voltage and it would do no harm. All that was good for the time, but it just happens that that generator manufacturer is not in business now; perhaps he had the wrong idea.

There was a reason, then, for having high generator reactance, because 30 years ago we had no oil switches whatever when we started operating on 40,000 volts, nothing but fuses and air switches. The average interruption at that time was some 25 to 30 min. We made up our minds that this had to be remedied, so we made up some improvised oil switches. With the subsequent improvements in switches and relays, results have been accomplished that are really wonderful. Now we are striving to maintain the generated voltage by high-speed excitation and other means.

That matter of cutting the system into parts, which has been mentioned by one of the speakers, was tried 25 or 30 years ago when we tied the northern end of the Pacific Coast system to the south switch and a man stood at that switch day and night and separated it by pulling a lever. Of course operations are now going forward in an improved way. Some 50 different power plants feeding into the San Francisco Bay District are so connected that in case of trouble they can be divided into parts.

I should like to call attention to the synchronous condenser value. It has, first, a value in increasing the power capacity of a transmission line. That is, a 220-kv. transmission line has a *normal* capacity, as I call it, of transmitting power of about 120,000 kw. at a constant voltage. That is, when that amount of power is being transmitted over a transmission line the charging current is just such as to give a uniform voltage over the transmission line, which could theoretically go around the world and end up with the same voltage you start with.

The charging current of a transmission line is some 25,000 kv-a. per hundred miles. It used to be thought that that was a liability, but if you match that 25,000 charging kv-a. with 25,000 to 30,000 of synchronous-condenser kv-a. you make that charging current an asset.

The second advantage of the condenser is that it increases the stability of the transmission system.

The third value of the condenser is not generally recognized. I will refer to the Pacific Gas & Electric Company system, comprising more than 50 different power plants feeding a general receiver area. Before we had a main synchronous-condenser control station it was necessary for the load despatcher to telephone to 50 different operators as to how much kv-a. they should put into the system at different times of the day. And it became almost impossible to handle that job because one plant would try to slip the charging kv-a. onto the other fellow. At the present time there is 80,000 kv-a. in the central system condenser station feeding into it, and the load despatcher tells the power stations what kilowatts he wants delivered and the voltage regulation is all done by the one condenser station. The load despatcher told me a few years ago that the old system would be practically impossible to operate, but now he has one station which can control the voltage of the whole system as he desires. Now the instructions are simpler and the whole system operates much better and probably a very large system like that would be impossible to operate without synchronous condensers, if they were of value, for no other reason than to simplify the method of operation of voltage regulation.

**F. C. Hanker:** The ultimate aim of any power system is to maintain continuity of service, and these recent modifications are for the purpose of improving the service record. Mr. Baum has mentioned that you have to remove the line or section of the circuit in trouble off the system just as quickly as possible. If you do that within a tenth of a second, or within that order of time, your general problem of operation and maintaining service will be very much simplified.

One of the problems that resulted from the study of system conditions was the method of calculation. These are more involved, sometimes, than the systems themselves and Mr. Bergvall is to be commended on the use he has made of the simple, mechanical model, in simplifying the analysis of the more complicated systems. The simple model has done more to visualize to the operating man the conditions that exist in his system than any other method; far more than could be done by any amount of discussion.

At the last Pacific Coast Convention the operating men, in connection with the manufacturers, presented a paper showing two years of operation on the Edison System. If we had similar data on other systems we could soon set up a definite measuring stick to help tell us where we are going and where we would land on systems of two and three times present capacity. It wont be many years before our systems are going to double and quadruple and when that time comes we are not sure whether the present system of operation will be desirable and effective, or whether we shall have a modified system, which may be either a combination of the present with a new, or perhaps an entirely different one. I think the operating engineers should give more thought to that phase of the matter because it does offer a problem of considerable importance.

**A. E. Bauhan:** Not so many years ago the question of stability was practically unrecognized as a cause of major system troubles. In my experience with the Baltimore systems some years ago, we had numerous cases where ordinary 13,000-volt feeder short circuits were given the blame for major outages. These short circuits in themselves were really minor troubles and should have cleared by relay action without serious interruption of service, but for reasons not clearly understood at the time, general disruption of the whole system with loss of interstation ties and main transmission followed. It was later recognized that with the system connections then in use there was a condition of transient instability which was the real cause of the major trouble. Since then more recognition has been given to this matter generally and with better understanding of the conditions influencing stability under short-circuit conditions, system operation is being improved.

When the particular interconnection referred to in this paper was conceived a few years ago the question was raised as to what the stability limit would be, and the figure mentioned was quite different from the one that has recently been determined. As time went on, and new calculations were made, lower and lower limits were reported. Later the figures from various sources became consistent with each other and there was more assurance that the approximately correct answer had been reached. This is significant of the progress which has been made in determining maximum power flow and the mechanical analog which has been explained here today has had much to do with clarifying this problem.

Fortunately, with regard to the Pennsylvania-New Jersey interconnections, distances are short and the question of stability did not affect the economic feasibility of the project, the stability limits being considerably higher than the loads which were necessary to justify the interconnection. However, on long-distance transmission of large amounts of power, the stability limit affects the number of circuits and the amount of synchronous-condenser capacity and therefore the cost of a major element of the delivered power cost. Its accurate prediction in such cases is of great importance in determining the economy of the project.

With regard to the question as to the effect of voltage dips in one part of the system being transmitted to another part of the system, my view is that we will have some trouble from that source. There will doubtless be a larger number of voltage dips on the individual systems than would have occurred without interconnection. However, I do not regard such voltage disturbances as being important. To the lighting customers they are mere flickers of the lights. To the power customers whose switches are equipped with instantaneous low-voltage releases, the more serious voltage disturbances will cause interruptions. In those applications where continuity is inportant the instantaneous low-voltage release has no place in any event and the remedy lies in seeing that all such applications have time delays on any necessary low-voltage releases.

**P. H. Robinson:** The Westinghouse Electric & Manufacturing Company has conducted extensive tests and development work on the regulating equipment for the condensers being supplied for the Westmoreland Substation. In order to handle the heavy field currents necessary to build up the reactive kv-a. at a high rate of speed, special regulator contactors were developed and will be used in connection with a suitable system of relays for control.

The exciters are of special design, having a laminated frame and comparatively few field turns. Laminating the frame was found necessary in order to reduce the retarding effect of eddy currents on the building up of the flux in the exciter. If a solid frame were used it would not be possible to obtain such an extremely high rate of building up of the exciter voltage.

While we were conducting tests on a synchronous condenser, a phenomenon occurred which was quite interesting. It was found for the particular machine under test that three or four times normal field current would cause hunting and finally make the condenser drop out of synchronism and stop suddenly. This heavy field current made the natural period of the machine identical to a natural oscillation existing in the supply system.

It might be well to investigate the possibility of such an occurrence on an actual system.

**A. F. Bang:** In underground systems in practically all large cities, nowadays, it is recognized as good practise to have reactance coils at both ends of a feeder. These coils not only limit the current that the switches have to take care of, but also, and this is the main point, keep up the voltage on the station busses between which the fault is located.

Now, when almost everybody realizes that this is the right thing to do in city systems, why is it almost standard practise to parallel on the high-tension side when it comes to transmission-line systems? I, for one, cannot see the logic of the situation. By not paralleling the transformers on the high-tension side, the transformers themselves will act as reactance coils to keep up the voltage on the generating station busses. A system of this kind has been used successfully for many years on the Pennsylvania Water & Power Company's 70,000-volt lines and we believe the system has many advantages, particularly for relatively short lines.

**Raymond Bailey:** The studies which have been made on the Coast where 220-kv. systems have been in operation for some time, and also those made in the East largely by engineers of the manufacturing companies, have proved very helpful. Considerable progress certainly has been made, but I believe we still have much to learn about stability of operation, and it is expected that in the future we will profit not only by further analytical studies that will be carried along, but also from actual experience of operation.

It seems to me to be of extreme importance, particularly in a system in which large blocks of power are transferred over great distances, to isolate faulty sections of the system with minimum time delay in order to prevent unstable operation. The development of circuit breakers that open the circuit more quickly or development of relay protective schemes that do not depend upon a time delay in their operation may lead to reduction in the length of time required to clear faults from systems.

Our efforts in designing the relay protective system for the Conowingo project have been to secure means for isolating faulty sections as quickly as possible under all conditions. This condition, along with the high-speed excitation on the Conowingo generators and on the condensers at the receiving end, we believe will do much to insure stability of operation.

**R. C. Bergvall and P. H. Robinson:** Mr. Smith has brought up the question of governor action during system transients. The transients produced by severe short circuits are of such brief duration that normally the governors will not appreciably change the input to the prime movers until after the disturbance has been cleared. A number of cases is known where disturbances and the accompanying switching operations have set up severe hunting between interconnected stations whose governors were not properly adjusted. The solution of this problem is proper governor adjustment and is beyond the scope of the mechanical model analysis. Wattless short circuits that are severe enough to cause the generators to speed up indicate that the short circuits have been of the 3-phase type, entirely removing the tie between the generators and the load and the speeding up indicates that loss of synchronism has occurred. The time lag in the relays has been added to the circuit breaker operating time in making the analysis.

Mr. Bang mentioned using reactors in transmission lines similar to the present practise which has proved beneficial on lower-voltage circuits. Generally, there are only two or three high-voltage transmission lines tying together two systems. With reactors placed in these lines the loss of one circuit greatly increases the amount of reactance through which synchronism must be maintained, and the reactors even though they cushion the initial short circuit will be detrimental due to decreasing the strength of the tie line. On lower-voltage circuits the reactors are generally used in feeders that are not depended upon for furnishing synchronizing power and the reactors are beneficial in reducing the severity of the short circuit.

Mr. Bang brought up the question of using transformers as a part of the line to serve as reactors and limit the short circuits. There are undoubtedly cases where such practise would be of value but it is impossible to give general conclusions as each case would have to be considered individually.

The use of quick-response excitation systems on the important generating stations in an interconnected system will be of great value in maintaining stability during transient disturbances.

**D. M. Jones:** With the mechanical device described by Messrs. Bergvall and Robinson it would appear that once a given system is reduced to an approximate mechanical counterpart it would be very easy to obtain data on the relative effect of variation in certain basic factors; also, in a sense, the analog is free from the small cumulative error inherent in step-by-step calculation processes. Finally, it has a certain visual quality which is of value in providing general images of what takes place on a system during disturbances.

The analog in turn has its inherent difficulties. It is evident that it is devoid of large amounts of friction. It might at first be thought that such friction as might exist would be very closely akin to the damping that actually occurs in the system. Two comments on that might be of interest.

Of course to the small degree that there is any friction it is not an exact counterpart of the damping, as friction is practically a constant force and damping is a force which should vary with the rate of motion of the levers.

The other thing that may be of more interest is that it is a matter of both experience and test that certain system conditions, especially those including high-resistance lines, result in a considerably reduced or even at times an actual negative damping. This condition not only causes mechanical friction to be at basic variance with the true requirements, but also suggests a point of departure between the analog and the facts.

The presence of appreciable series system resistance also results in a condition which is not rigidly represented by the symmetrical simplicity of a generator lever and a load lever crosstied with a spring with the resulting maximum mechanical torque angle of 90 deg.; for such resistance tends to increase the real maximum load angle for the generator and at the same time to decrease it for the load to values departing from the basic value above mentioned.

Also, to the degree that salient-pole machines are present on a system, a condition arises which does not coincide with that assumption of a sine wave torque-angle curve for all machines, on which the analog is based, because salient-pole machine torque-angle curves are never true sine curves and may depart appreciably from them as has been brought out in *Synchronous Machines I*, by R. E. Doherty and C. A. Nickle, (see A. I. E. E. TRANS., Vol. XLV, 1926, p. 942).

Again, although mechanical simplicity suggests the representation of short-circuit disturbances by a fixed lever length to which is applied a fixed force, which is the equivalent of a constant voltage at the short, and a fixed loss therein, the actual voltage and loss are never constant throughout the duration of the short circuit and often vary considerably.

These comments in suggesting certain limitations in the mechanical analog are not offered in condemnation of this most interesting device, but rather to point out the probability that there will be certain system conditions where the results obtained from it will be satisfactory and others where the errors may be unduly large, and to express the hope that work on it may continue to the end that the connection between the type of system condition and the resulting error may be thoroughly established.

Mr. Smith mentioned overvoltage with regard to excessive excitation applied to synchronous condensers. He has mentioned that very justly. That is one of the distinct limitations of excitation to abnormal degrees. In the condenser on the Conowingo system this is taken care of by the regulator, and of course that maximum voltage on the exciter disappears very quickly, so that the amount of excitation that has to be reduced is not a thousand volts but that equivalent refers to the double field current, and as has been pointed out you are up against a condition which is influenced by two factors: how quick your equipment is in controlling the overvoltage, and the degree of overvoltage which the equipment itself would produce on the actual system.

I wish to substantiate the remarks made by Mr. Bergvall about the lightning-arrester question. It was felt that the maximum voltage which the lightning arrester would allow was considerably lower than the voltage which might occur on the line and therefore that its installation was justifiable.

I might make one minor comment with regard to a remark that Mr. Bang made. If, by use of reactance in any position you can materially reduce the disturbance without materially reducing the capacity of the synchronizing path you have done a very good thing. Now on our network it is probable that when you put in reactors you have not materially reduced the synchronizing path in general, as the thing is a pretty widespread network, while the reactor is very effective in reducing the short circuit. Furthermore if you had any system and short circuits of such a nature that you could control the magnitude by putting in reactance in such a way that you didn't influence the synchronizing path, it would be of advantage. That might be one way of obtaining certain benefits in stability. You could limit the path of the fault current probably without limiting the path of the power flow, and that would be of advantage.

**R. C. Bergvall and P. H. Robinson:** With reference to Mr. Jones' discussion, we recognize that friction is not an exact counterpart of damping, but both of these forces are so small that in an analysis of this type they can be neglected. In mots systems of sufficient magnitude to warrant a stability study no appreciable error is introduced by neglecting the series resistance as it amounts only to 1/10 or 1/12 of the reactance. It is true that salient-pole synchronous machines deviate somewhat from the sine-wave torque-angle curve for steady-state conditions, but during transients we are concerned with the characteristics of machines having the internal flux linkages maintained by means of quick-response excitation and the torque-angle characteristics approach the sine function. The demagnetizing action of the fault current in the armature of the synchronous machine is counteracted by the increase of excitation brought about by rapidly increasing the voltage applied to the field of the synchronous machine.

It is recognized that the application of a constant force to represent a fault is not exactly correct as pointed out in the paper. We must consider, however, that for the analysis of a complicated problem of this nature it is necessary to make certain assumptions which although not rigidly true, simplify the problem and do not affect the results to such a marked degree as to cause them to be incorrect in the general case. There is no method of predetermining the variation of the loss in a fault as there are so many factors involved that it would be impossible to exactly duplicate a condition. Any given or assumed fault condition can be analyzed and its effect upon the system determined.

The stability study has indicated the desirability of using quick-response excitation systems on the large generating units to maintain internal voltage under fault conditions. The value of such a scheme has been recognized for some years but only recently has been put into practise.

# Squirrel-Cage Rotors with Split Resistance Rings

BY HANS WEICHSEL[1]
Fellow. A. I. E. E.

*Synopsis.—The characteristics of a squirrel-cage induction motor are investigated when the resistance rings are provided with cuts 360 electrical deg. apart and the cuts in the front ring are displaced against those in the back ring by 180 electrical deg.*

*A theoretical investigation is given, which leads to the conclusion that splitting the rings results in an equivalent ring resistance which varies with double-slip frequency in the ratio of one to three; and the average ring resistance is twice what it was before the rings were cut. The variable rotor resistance effects a periodic fluctuation of the line current and rotor speed. The fluctuations have double-slip frequency. The theoretical conclusions are checked by tests and oscillograms. Test results show that the splitting of the rings is followed by increased rotor leakage, which results in a starting torque smaller than that corresponding to the increased resistance and original leakage.*

* * * * *

WHEN the starting torque of a squirrel-cage induction motor is not sufficiently high, the remedy often suggested is to divide each resistance ring by aid of saw-cuts into half as many sections as there are poles, the saw-cuts in the front ring being displaced against those in the back ring by an angle corresponding to one-pole pitch (180 deg.). A developed view of a four-pole squirrel-cage arranged in this manner is diagrammatically represented in Fig. 1.[2]

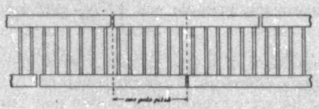

FIG. 1

The squirrel-cage rotor with its rings modified in this manner offers a resistance higher than an identical squirrel-cage with uncut rings. Below, it will be determined how much that part of the squirrel-cage rotor resistance which is due to the rings only is increased by cutting the rings. It will be found that a squirrel-cage with cut rings offers an *average* ring resistance equal to twice the resistance of the original uncut rings. A proof for this is as follows:

First, it is necessary to consider the current distributions and losses which take place in a squirrel-cage of the standard construction, using solid end rings, or so called resistance rings. Fig. 2 represents the current distribution in a two-pole squirrel-cage rotor with solid rings. In drawing the current distribution, it has been assumed that the ampere conductors on the stator follow a sine-law distribution in space. Strictly speaking, such a distribution exists only when the stator has an infinite number of phases and slots; but even for a finite number of phases and slots the above distribution is approached. For a sine-shaped stator ampere-conductor distribution, the rotor-current distribution must also follow the sine law. The rotor ampere-conductor distribution rotates in respect to a fixed point on the rotor with a speed corresponding to slip frequency. The shape of the distribution remains unaltered. In other words, Fig. 2 can be considered as showing the current distribution in the squirrel-cage at any moment. This distribution remains independent of time.

If the distance between two adjacent rotor bars is $\delta$ electrical deg., and the rotor has an even number of bars per pole, the current in the different bars has the following values:

$$\text{Current in bar } I_1 = I \times \text{sine} \frac{\delta}{2}$$

$$\text{Current in bar } I_2 = I \times \text{sine } \delta + \frac{\delta}{2}$$

$$\text{Current in bar } I_3 = I \times \text{sine } 2\,\delta + \frac{\delta}{2} \quad \text{etc.}$$

These equations are vectorially represented in Fig. 3.

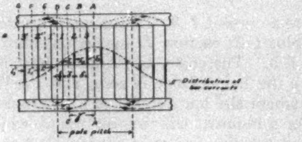

FIG. 2

The vectors 1–2, 2–3, 3–4, 4–5 are alike and are equal to $I$. (*i. e.*, the maximum current which any of the bars can carry), and are displaced against each other by the angle $\delta$. All these vectors form a polygon, the circumference of which approaches the value $2\,Z \times I$, where $Z$ is the number of squirrel-cage bars for one pole. The radius of a circle circumscribing this polygon is, therefore, given by the equation:

$$r = \frac{2\,Z\,\hat{I}}{2\,\pi} = \frac{Z\,\hat{I}}{\pi} \tag{1}$$

---

[1] Consulting Engineer, Wagner Electric Corp., St. Louis, Mo.

[2] This scheme was originally suggested by Zieglke, see Electric Motors, by H. M. Hobart, p. 314.

*Presented at the A. I. E. E. Regional Meeting, St. Louis, Mo., March 7-9, 1928.*

As shown above the current in bar 1 is $\hat{I}$ sine $\frac{\delta}{2}$.

The current in bar 2 is $I$ sine $\left(\delta + \frac{\delta}{2}\right)$, and the current in bar 3 is $\hat{I}$ sine $\left(2\,\delta + \frac{\delta}{2}\right)$. From Fig. 3 it will be seen that these current values are represented by the lines 2–7, 3–8, 4–9, etc. In other words the projection of the lines 1–2, 2–3, 3–4, 4–5, etc., on the horizontal diameter 0–1 represents the bar currents $I$–1, $I$–2, $I$–3, etc.

From the distribution of the bar currents, as given in Fig. 2, the distribution of currents in the ring can be derived.

For the purpose of symmetry (see Fig. 2), it is permissible to say the current $I$–1 and the current $I$–1′ form one circuit. In the same manner the current $I$–2 in bar 2 completes its circuit with current $I$–2′ in bar 2′, etc. Consequently, the section $A$ of the ring does not carry any currents at all; while the section $B$ carries a current $I$–3; the section $C$ carries the current $I$–3 plus $I$–2; section $D$ carries current $I$–1 plus $I$–2 plus $I$–3. Therefore, the ring current is a maximum where the bar current is zero, and the ring current is zero where the bar current is a maximum. Considering for a moment the ring section $C$, which carries bar current $I$–3 plus $I$–2, we see from Fig. 3 that the current in this section is equivalent to the projection of the chord 2–4 on the base line 0–1. But this can also be considered as the projection of the radius $r$ = 0–2 on the base line 0–10. Thus the current in ring section $C$ can be expressed as

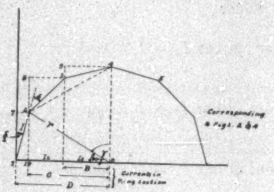

FIG. 3

$$I_c = r\cos(90 - \gamma) = r\sin\gamma \qquad (2)$$

where $\gamma$ is the angle the radius 0–2 forms with the radius 0–4, which is identical to saying the angle $\gamma$ is the distance, measured in electrical deg., from the center of section $C$ to the center of section $A$. By equation (2) it is demonstrated that the current distribution in the rings follows a sine curve, being zero at the point $A$. As seen, previously, the current distribution in the bars follows a sine curve, being zero at the point $D$. Points $D$ and $A$ are 90 deg. displaced from each other. Therefore, if both curves refer to the same starting point, one of the curves is a sine curve and the other is a cosine curve. Substituting in equation (2) the value for $r$ from equation (1), it follows:

$$I_\gamma = \frac{Z\,\hat{I}}{\pi}\sin\gamma \qquad (3)$$

which expresses the ring current at any section $\gamma$ as function of the maximum bar current $\hat{I}$. The loss due to the ring current is at any point proportional to the square of the current. Consequently the loss at any point is obtained by squaring equation (3) and multiplying it with a coefficient $k$, which takes care of the resistance of the ring section under consideration. The loss at any point is, therefore:

$$\frac{Z^2\,\hat{I}^2}{\pi^2}\sin^2 r \times k \qquad (4)$$

The total ring loss is the integral of equation (4) and is given by equation:

$$\text{Loss in one ring per pole} = 2\int_{r=0}^{r=90}\frac{Z^2\,\hat{I}^2}{\pi^2}\sin^2 r\;k\;dr \qquad (5)$$

$k$ = resistance of a ring portion corresponding to a unit angle. Therefore, if $k$ is the resistance of one ring spanning an arc corresponding to one pole pair ($2\,\pi$), we obtain:

$$k = \frac{R}{2\,\pi} \qquad (6)$$

The solution of the integral part of equation (5) is:

$$2\int_{r=0}^{r=90}\sin^2 r = 2\left(\frac{1}{2}\,r - \frac{1}{4}\sin 2\,r\right)^{\frac{\pi}{2}} = \frac{\pi}{2} \qquad (7)$$

Consequently the losses in one ring per pole

$$= \frac{\pi}{2}\,.\,k\,\frac{Z^2\,\hat{I}^2}{\pi^2}$$

Substituting $k = \frac{R}{2\pi}$ from equation (6), it follows:

losses in one ring per pole =

$$\frac{R}{2\,\pi}\cdot\frac{\pi}{2}\cdot\frac{Z^2\,\hat{I}^2}{\pi^2} = \frac{R\,Z^2\,I^2}{4\,\pi^2}$$

and the losses per pole pair and both rings equal:

$$\frac{R\,Z^2\,I^2}{\pi^2}\,.\text{ if }\bar{I} = \hat{I}\,\sqrt{2} \qquad (8)$$

The losses in both rings per pole pair equal:

$$\frac{R\,Z^2\,\hat{I}^2\,2}{\pi^2} \qquad (9)$$

$R$ = resistance of ring spanning two-pole pitches
$Z$ = number of squirrel-cage conductors per pole

$I$ = effective rotor-bar current per pole

The laws established so far are well-known and refer to the current distribution and losses in the bars and rings of a squirrel-cage whose rings are solid, (Fig. 2). The relations are not quite as simple for a squirrel-cage with slotted endings (Fig. 1).

Figs. 4 and 6 show a two-pole squirrel-cage winding with end rings split in the manner described. It has been shown above that the current distribution in the squirrel-cage bars must follow a sine law as long as the current distribution in the stator follows the sine law. The current distribution in the bars is given by the sine curve 2–3–4 (Fig. 4) for the moment when the rotor bar currents are so located that the maximum bar current coincides with the slot $A$ in the ring 1. This distribution is identical to that shown in Fig. 2. It is evident that the ring currents in Fig. 4 must be distributed as shown, which when plotted in a coordinate system as a function of space gives Fig. 5.

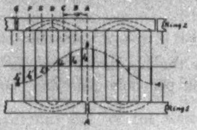

Fig. 4

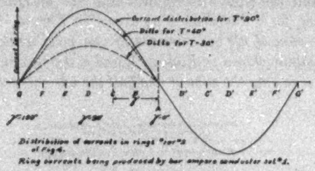

Fig. 5

Conditions change materially if the moment is considered when the sine-shape distribution of the bar currents is so located that the bar carrying no current coincides with the cut $A$ in ring 1, as shown in Fig. 6. With the bar current in this distribution, it is no longer possible that the current $I$–1 and $I$–1′ close symmetrically in rings 1 and 2, as found for Fig. 4. The only symmetrical ring distribution possible with the symmetrical bar distribution is that given in Fig. 6, *i. e.*, section $F$ in ring 2 must carry the bar current $I_1$. The section $E$ carries bar current $I_2$ plus $I_1$; section $D$ carries $I_1$ plus $I_2$ plus $I_3$. Section $C$ carries $I_1$ plus $I_2$ plus $I_3$ plus $I_4$. Section $B$ carries $I_1$ plus $I_2$ plus $I_3$ plus $I_4$ plus $I_5$, and, finally, section $A$ carries the sum of all bar currents of one pole, *i. e.*, $I_1 + I_2 + I_3 + I_4 + I_5 + I_6$.

A more general expression for the currents in the ring section with a bar-current distribution (Fig. 6) is obtainable as follows:

Vectors 1–2, 2–3, 3–4, 4–5, 5–6, etc. (Fig. 7) represent the maximum current in any of the rotor bars. Each vector is drawn against its preceding vector under an angle $\delta$ equal to the displacement of the bars against each other. The vector 1–2 is shown displaced against the vertical 1–7 by an angle $\frac{\delta}{2}$. The current $I_1$ in bar 1 is consequently given by the distance 2–7, and the current in $I_2$ in bar 2 is given by the vector 3–8, etc.

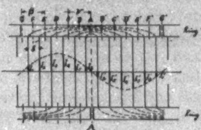

Fig. 6

In other words the bar currents are the projections of the vectors 1–2, 2–3, etc., on the base line 0–1′. So far the diagram is identical to Fig. 3. The current passing through the ring section $F$, as shown above, is equal to the bar current $I_2$. Consequently, it is given by the length 2–7 or 1–10 (Fig. 7), which is the projection of the vector 1–2 on the base line. The current through the ring section $E$ is the sum of bar current $I_1$ and $I_2$. It is consequently given by the length 1–11, which is the projection of the vectors 1–2 and 2–3.

If the currents in the different sections, $A, B, C, D, E,$ and $F$, are plotted as function of their space location, a current distribution in the ring is obtained as shown in Fig. 8. A glance at Figs. 6, 7, and 8 shows the current distribution in the rings must be related in some manner to a sine law. The exact relations are derived mathematically as follows:

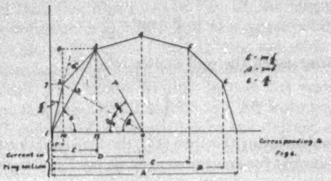

Fig. 7

In Fig. 6 the center of the ring section $E$ is $\beta$ electrical deg. displaced against the point $G$. It follows that in this case $\beta = 2\,\delta$. In the same manner the ring point $D$ is displaced by an angle $\beta = 3\,\delta$, etc. In Fig. 7 the angle $\beta$, of Fig. 6 appears as angle 1–0–3, if the ring section $E$ is under consideration; or an angle 1–0–4 if point $D$ is under consideration, etc. From triangle

1–0–3, it follows that the side 1–3 is given by the equation:

$$(1\text{–}3) = 2\,r \sin \frac{\beta}{2} \tag{10}$$

As the ring current in section $E$ is a projection of the vector 1–3 on the base line,

$$I_\beta = 2\,r \sin \frac{\beta}{2} \,.\, \cos \epsilon \tag{11}$$

But angle $\epsilon$ is related to the angle $\beta$,

$$\epsilon = 90 - \frac{\beta}{2} \tag{12}$$

as can be seen from the triangle 1–0–12. Consequently the cosine of angle $\epsilon$ can be expressed as a function of angle $\beta$. $\cos \epsilon = \cos \left( 90 - \frac{\beta}{2} \right) = \sin \frac{\beta}{2}$ (13)

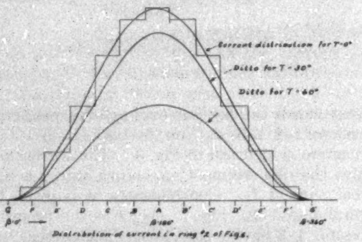

Fig. 8

and this value substituted in equation (11) gives

$$I_\beta = 2\,r \sin^2 \frac{\beta}{2} \tag{14}$$

Making use of the well-known relation

$$2 \sin^2 \frac{\beta}{2} = \left( 1 - \cos \frac{\beta}{2} \right) \tag{15}$$

and substituting this into (14), the final equation for the ring current for an arrangement as per Fig. 6 is given,

$$I_\beta = r\,(1 - \cos \beta) = \frac{Z\,\bar{I}}{\pi}\,(1 - \cos \beta) \tag{16}$$

This equation gives the ring current in a split ring as function of the angle $\beta$ (Fig. 6), and which when plotted in coordinate system gives the curve of Fig. 8. Consequently, the loss at any point of the ring is obtained by squaring equation (16) and multiplying it with the coefficient $k$, which takes care of the resistance of the ring section under consideration, in the manner explained.

The loss at any point of the ring is, therefore,

$$\bar{I}_\beta^2\,k = r^2\,(1 - \cos \beta)^2\,k \tag{17}$$

The total ring loss must be the integral of this equation, *i. e.*,

$$\text{loss in one ring per pole pair} = \int_{\beta=0}^{\beta=360} r^2\,k^2\,(1 - \cos \beta)^2\,d\,\beta$$

$$= k\,r^2 \left[ \int_0^{360} d\,\beta + \int_0^{360} \cos^2 \beta\,d\,\beta - \int_0^{360} 2 \cos \beta\,d\,\beta \right]$$

$$= k\,r^2\,[2\,\pi + \pi + 0 - 0] = 3\,\pi\,r^2\,k \tag{18}$$

Consequently the loss in one ring per pole pair equals $3\,r^2\,k$, or loss per pole pair and both rings equal

$$6\,\pi\,r^2\,k \tag{19}$$

Substituting $k = R/2\,\pi$ from equation (1) and $r = \dfrac{Z\,\bar{I}}{\pi}$ from equation (6), we find, losses for both rings per pole

$$\text{pair} \quad = \frac{3\,R\,Z^2\,\bar{I}^2}{\pi^2} = \frac{3\,R.Z^2\,\bar{I}^2\,.\,2}{\pi^2} \tag{20}$$

This equation compared with (8) shows that the ring loss for a current distribution (Fig. 6) is three times as large as the ring loss for a current distribution, (see Figs. 4 & 5).

From the above it follows that *the maximum ring current, for a distribution as shown in Figs. 6, 7, and 8, is the sum of all bar currents of one pole; while for the distribution shown in Figs. 3, 4, and 5, the maximum ring current is only the sum of one-half the bar currents of one pole.* The losses in one ring must vary from time to time: At one moment the distribution of the ring current in ring No. 2 is that given in Fig. 4, and 90 electrical deg. later the current distribution in the ring No. 2 and bars is as shown in Fig. 5. In order to determine the actual loss in the rings, it is to be remembered that a rotating sine-shaped field can always be considered as being made up of two alternating sine-shaped stationary fields, which are located at right angles to each other and the alternations of which have a 90 deg. time displacement. Consequently, sine-shaped distributed

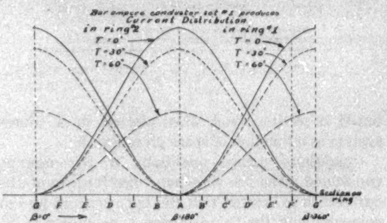

Fig. 9

rotating ampere conductors (bar currents are under discussion) can be considered as being made up of two sets of ampere conductors:

Set No. 1, whose axis is located as per Fig. 4, *i. e.*, the maximum of the ampere conductors coincides with the slot *A* in the ring.

Set No. 2, whose axis is located as per Fig. 6, *i. e.*, it is 90 electrical deg. displaced from the slot *A*.

The ampere conductors of each one of these two sets must vary in time according to the sine wave, or cosine law, and the amperes in a given section of a ring must also vary with time in accordance with the sine or cosine law. For instance, for Fig. 4 the ring current distribution in space is given by Fig. 5. For the time $T = 0$, it has been assumed that the current is zero; for the time $T = 90$ deg., the current distribution has reached its maximum; and for the time $T = 30$ and $T = 60$, the distributions lie between the two mentioned extremes.

In a similar manner, current distributions in a split ring vary from time to time. For the time $T = 0$ the distribution is represented by the heavy curve in Fig. 8.

Fig. 10

This figure also shows the distribution for the time $T = 30$ deg. and $T = 60$ deg. For the time $T = 90$ deg., the current distribution is zero and is equivalent to the base-line of Fig. 8 diagram.

In discussing the current distribution in a split ring, reference was made to ring No. 2 in Fig. 6. It remains to be seen if the same current distribution also exists in ring No. 1 of Fig. 6. For reasons of symmetry, the current distributions in rings Nos. 1 and 2 must have the same general shape. However, the curve representing the current distribution in ring No. 1 must be displaced 180 electrical deg. against the curve representing the current distribution in ring No. 2, because it is seen that the current in ring No. 1 is zero at point *A* and the current in ring No. 2 is a maximum at point *A*. The distributions of rings Nos. 1 and 2 for a given time instant are given in Fig. 9.

For the unsplit ring, (Figs. 3, 4, and 5,) the current distributions in corresponding sections in rings Nos. 1 and 2 are the same and are not displaced against each other.

In reality the ring distributions, as shown in Figs. 4 and 6, occur simultaneously. Consequently the resultant current distributions in each ring must be the sum of the currents in a given ring section, as found from Figs. 4 and 5, and the current in the same ring section as found from Figs. 6 and 9.

In this manner the distribution of the currents in ring No. 2 is obtained as shown in Fig. 10, where curve *I* represents the distribution in ring No. 2, due to the ring currents produced by the bar ampere conductor set No. 1, which, in turn, corresponds to the arrangement shown in Fig. 4. The curve II in Fig. 10 represents the current distribution in ring No. 2 due to ring currents produced by the bar ampere conductor set No. 2, which, in turn, corresponds to the arrangement shown in Fig. 6. Curve III, finally, represents the sum of the ordinates of curves I and II and represents for a certain time instant the resultant current distribution in ring No. 2. For a different time instant, the resultant ring distribution has a different shape, as follows:

As the time when ampere conductor set No. 1 is zero, ampere conductor set No. 2 is a maximum. The resultant distribution in ring No. 2 at this moment must be, therefore, as shown in Fig. 8, curve marked $T = 0$. Similarly, for the instant when ampere conductor set No. 1 is a maximum, ampere conductor set No. 2 is zero, the resultant distribution in ring No. 2 is, for this moment, as the curve marked $T = 90$ in Fig. 5. In Fig. 10, a time moment $\alpha = 45$ deg. has been selected, so as to have neither curve I nor II equal to zero. For this time moment, the maximum value of curves I and II happens to be equal to 70.7 per cent of the absolute maximum which they reach for the time $\alpha = 0$, and $\alpha = 90$ deg.

It must be clearly understood that for any other time instant than that illustrated in Fig. 10, the magnitude of the ordinates of curves I and II changes, while the relative shape of curves I and II does not alter. On the other hand, the shape and the magnitude of curve III alters with time. At any instant the resultant current flow in any ring section say, for instance, section *C*, consists of a current due to the current corresponding to curve I, *i. e.*, equal to $a$, and a current due to curve II, *i. e.*, equal to $b$. The total instantaneous current in ring section *C* is, therefore, $a + b$. The instantaneous loss in the ring section *C* is proportional to the square of the resultant current and, hence, is proportional to $(a + b)^2$.

If a corresponding ring section *C'* is selected—which is so located that its distance from the symmetry line *A* is the same as the distance of the point *C* from the symmetry line *A*—the instantaneous current in section *C'* is $b - a$, and the loss in this section is proportional to $(b - a)^2$. Consequently, it can be said: Loss in section *C* proportional to $(a + b)^2$

$$= (a^2 + b^2) + 2\,a\,b.$$

Loss in section $C'$ proportional to $(a - b)^2$

$$= (a^2 + b^2 - 2\,a\,b).$$

The combined loss in sections $C$ and $C'$ is the sum of the losses in $C$ and $C'$ and is given by:

$$\text{Loss in section } C \text{ and } C' = 2\,(a^2 + b^2). \qquad (21)$$

This equation demonstrates that *the sum of the instantaneous losses in any two symmetrically located ring sections equals the sum of the losses produced independently in each section by the ring currents a and b.*

FIG. 11

Consequently, the total losses in ring No. 2, at any moment, is equal to the sum of the instantaneous ring losses due to currents I and II. As the magnitude of the currents represented by curve I, Fig. 10, changes in time according to a sine law, it follows that the losses due to these ring currents change in time as,

$$L_1 = \bar{L}_1 \sin^2 \alpha \qquad (22)$$

where $\bar{L}_1$ is the maximum loss which occurs in the ring, that is, which occurs at the time $\alpha = 90$ deg. Similarly, the currents corresponding to the distribution curve II, Fig. 10, change in time in accordance with the cosine law. The losses due to the currents corresponding to curve II are given,

$$L_2 = \bar{L}_2 \cos^2 \alpha \qquad (23)$$

where $\bar{L}_2$ is the maximum loss which occurs in the ring due to the bar ampere conductor set No. 2. Previously it was shown by equation (**20**) that a fixed relation exists between $\bar{L}_1$ and $\bar{L}_2$, and that $\bar{L}_2$ is three times as large as $\bar{L}_1$. In other words,

$$\bar{L}_2 = 3\,\bar{L}_1 \qquad (24)$$

The total loss in ring No. 2 at any time $\alpha$ must be the sum of the losses given by equations (**22**) and (**23**). Substituting for $L_2$ the values from equation (**24**), we obtain,

$$\begin{aligned} L_1 + L_2 &= L_1, \sin^2 \alpha + 3\,L_1 \cos^2 \alpha \\ &= L_1\,(\sin^2 \alpha + \cos^2 \alpha + 2 \cos^2 \alpha)\; L_1 + L_2 \\ &= L = 1 + 2 \cos^2 \alpha \qquad (25) \end{aligned}$$

The results of equation (**25**) are graphically represented in Fig. 12. It will be seen that the resultant loss in ring No. 2 fluctuates between the extremes of $3 \times \bar{L}_1$ and $\bar{L}_1$. The time intervals between two successive maxima correspond to one-half slip periodicity.

So far the losses were derived for the current distributions existing in ring No. 2. It was shown that the current distribution in ring No. 1 due to bar ampere conductor set No. 2 is the same as in ring No. 2, but is 180 deg. displaced in space against the distribution in ring No. 2, as shown in Fig. 9.

The ring current distribution in rings Nos. 1 and 2, due to the bar ampere conductor set No. 1, are, however, identical in every respect.

Consequently the resultant current distribution in ring No. 1 is as shown in Fig. 11. In Fig. 10 the curve I passes through zero where curve II is a maximum, while in Fig. 11 curves I and II pass through zero at the same point. Selecting again two symmetrically located sections $C$ and $C'$ on the ring No. 1, the instantaneous currents in these ring sections are respectively $a$ and $b$. The losses in these sections are $(a + b)^2$, and $(a - b)^2$. Consequently, the law – that the resultant instantaneous losses are the sum of the instantaneous losses of the ring currents due to bar ampere conductor set No. 1 and the ring currents due to bar ampere conductor set No. 2,—also exists for ring No. 1; and the resultant losses in ring No. 1 must vary in time in accordance with the same law as the resultant losses in ring No. 2. The losses in rings Nos. 1 and 2, therefore, reach a maximum at the same time, and also reach a minimum at the same time. It can be stated that for a given effective bar current the losses in the split rings vary in the relation of 3 to 1 and have maxima at time intervals equal to one-half slip periodicity. In other words, the ring losses fluctuate in time with double-slip frequency.

Equation (**25**) gives the mathematical expression for the variation of the losses as function of time $\alpha$. This equation contains the factor cosine² $\alpha$. It is a well-known fact that the average ordinates of a cosine² $\alpha$ curve are one-half of the maximum ordinates. Consequently the average loss in the rings is given by the equation,

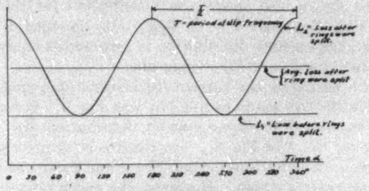

FIG. 12

$$(L_1 + L_2)_{\text{avg.}} = 2\,\bar{L}_1 \qquad (26)$$

This equation shows the important fact that the *average* ring loss in a squirrel-cage with split rings is two times as large as the losses in an unsplit ring, as long as the effective currents in the bars are kept constant.

As these laws are derived for the losses occurring with a given effective current in the bars, it is evident that the same laws also apply to the resistance which the split rings of the squirrel-cage offer. It is, therefore, correct to say *the ring resistance of a squirrel-cage with split rings varies in the ratio of 3 to 1 with a frequency of two times slip frequency. The average ring resistance is equal to two times the resistance of an unsplit ring.*

FIG. 13

Consequently with *absolutely constant rotor speed*, the effective value of the bar currents fluctuates with double-slip frequency, which in turn means that the rotor torque fluctuates with double-slip frequency. Such a condition exists when the inertia of the rotor and the driven machinery is very large and tends to keep the rotor speed constant in spite of the fluctuating torque which acts on the rotor.

On the other hand, when the rotor and the driven machine have infinitely small inertia and the mechanical load torque is held constant, the slip of the machine must vary periodically and the rotor bar currents remain constant in order to produce constant torque.

In the latter case, an oscillogram of the primary line current must show a constant magnitude of alternating current. In the former case, where the inertia is infinitely large, the oscillogram of the line current must show a variation of the a-c. value and the magnitude of this alternating current fluctuates periodically in time.

FIG. 14

In practise the conditions lie between the two extremes just discussed, that is, the speed and the current changes. As a rule these changes will not be found very objectionable.

The higher the average slip, the faster are the torque impulses, and the greater is the tendency for the machine to run at constant speed.

An oscillogram of the full load line current taken on a 7½-hp., four-pole, 60-cycle, 2-phase, 220-volt, squirrel-cage motor with split rings is shown in Fig. 14. The fluctuations in the magnitude of the line current is clearly shown in this oscillogram. Fig. 13 shows the line current on the same machine, but provided with a squirrel-cage without split rings. No fluctuations whatsoever are noticeable in this case in the magnitude of the line current.

At the same time that the oscillogram of Fig. 14 was taken, the slip on the motor was also observed and found to be 4.4 per cent. It was measured by the stroboscopic method, and the white cross on the pulley used clearly showed a periodic swing, indicating that the speed of the motor fluctuated. The relations on the motor under test were such that the inertia was not sufficiently great to damp out completely the speed fluctuations. The oscillogram shows that the time between two current maxima, *A* and *C*, equals approximately 11 times the time between two adjacent 60-cycle current maxima, *A* and *B*. Consequently, the periodicity of the "breathing" of the line current is 1/11 = 9.1 per cent or 9.1/4.4 = 2.06 times the measured slip frequency. The theoretical value of this ratio according to the above theory is 2. The agreement between test and theory is satisfactory.

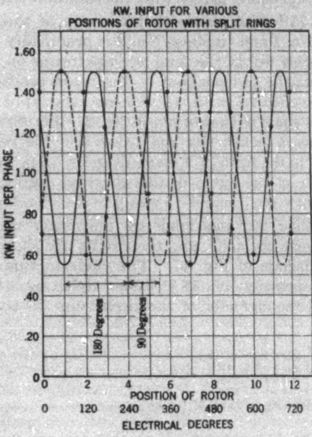

FIG. 15—7½ HP.—4 POLE—220 VOLT—60 ~2 Φ
1725 REV. PER. MIN.

Fig. 15 gives the kw. input to phases No. 1 and 2 when the rotor is locked and the rings are split. The results are plotted as function of rotor position. This plot shows that the kw. input of a given phase depends on the position of the rotor, and the maxima are displaced one-pole pitch or 180 electrical deg. This is in full agreement with the theory. The plot also shows that the maxima of phase No. 1 is displaced 90 electrical deg. against the adjacent maxima of phase No. 2. This also is in full agreement with the above theory, which shows that the minimum, or maximum, resistance of the squirrel-cage corresponds to two a-c. fields 90 electrical deg. displaced against each other.

From the maximum readings from phase No. 1, (corresponding to position 1-4-7), and the minimum reading of phase No. 2 (corresponding to the same rotor position), it is calculated that the equivalent rotor resistance expressed in primary turns is 1.62 for phase No. 1 and 0.565 for phase No. 2. Consequently, the ratio of resistance variation is 1.62/0.565 = 2.82. The theory showed that the rotor resistance, when only the rings are considered, must vary in the ratio of 1 to 3; but if the bars also are considered, the resistance naturally must vary in a ratio less than 1 to 3. The theory, therefore, agrees with the results found by test.

Fig. 15 further shows that the sum of the input to phase No. 1 and to phase No. 2 is practically constant or, in other words, the total average torque on the rotor is practically independent of the rotor position. For rotor position 1.6, 3.15, 4.7, 6.3, etc., the input to phase No. 1 is equal to that of phase No. 2. For one of these positions, a locked test was taken and the results are plotted in the form of a circle diagram (Fig. 16). The diameter of the circle of this diagram corresponds to 38 kv-a.

A similar test was made on the motor using rings which were not split, and the results are shown in the circle diagram of Fig. 17. The circle in this diagram has a diameter of 48.3 kv-a. Splitting the rings reduced the diameter of the circle from 38 to 48.3, or to a value of 79 per cent of the original value before the rings were split. This is equivalent to stating the leakage of the motor with split rings is 1/.79 = 1.27 times that of the same motor before the rings were split. Similar tests made on a number of other machines of different ratings and speeds also have shown an increase in leakage. It is, therefore, justifiable to say the splitting of the rings not only increases the average ohmic resistance of the rings in the ratio of 1 to 2, but also increases the leakage of the machine. Consequently, the actual gain in starting torque due to splitting the rings must be less than the increase in average rotor resistance. In the machine whose test data are recorded in this paper, the increase in leakage counteracted completely the increase in rotor resistance, and the net result was that the rotor with split rings had a starting torque corresponding to 10.68 kw., while the same motor with rings which were not split had a starting torque corresponding to 11.4 kw. Splitting the rings in this particular case increased the leakage so much as to more than counteract the increased rotor resistance. The starting torque of the motor provided with split rings was less than that of the motor with rings which were not split.

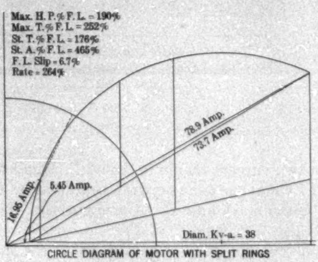

FIG. 16—7½ HP.—4 POLE—220 VOLT—60 ~2 Φ
1725 REV. PER. MIN.

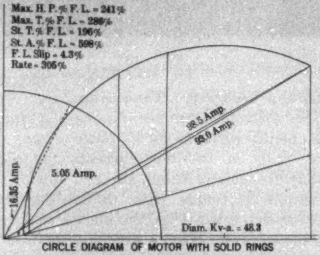

FIG. 17—7½ HP.—4 POLE—220 VOLT—60 ~2 Φ
1725 REV. PER. MIN.

The only beneficial effect obtained by splitting the rings in this case was a better torque per ampere. Before the rings were split, the torque per ampere was 11.4/9.85 = 1.16; and after the rings were split, the torque per ampere was 10.68/7.89 = 1.35. It is self-evident that the increase in leakage and rotor resistance must be followed by a decrease in maximum hp. output. For the tested machine, the circle diagrams show that the split rings decreased the maximum hp. to 78 per cent of the value which existed before the rings were cut. This figure, derived from the diagram, checked very closely with an actual brake test taken on the machine.

---

## Discussion

**D. D. Clarke:** I was very much interested in Mr. Weichsel's paper, because of the rather novel presentation of what, in the field, we think of as a repair trick to make a motor start a given load. I felt, in reading the paper, that Mr. Weichsel did not intend this as a normal production motor. The operating company has a contact with this motor that the manufacturer might not think important, and that is the varying current or breathing effect, as Mr. Weichsel puts it.

This breathing occurs three to five times per second and incandescent lamps are particularly sensitive to such breathing of the voltage. Even though it may vary only a half or one per cent, this, in a critical location, could make a very unsatisfactory condition on a public utility's lines. The difficult thing would be that replacement would be required to correct it. In a way, it is parallel to a trouble job on a wound-rotor motor where the secondary winding is open. This same sort of breathing action takes place because of the variation in the losses in the secondary of the induction motor.

Tampering by a repair man with the design features of a motor, does not improve conditions. In this case, the horsepower rating of the motor was reduced and the actual starting power was reduced.

**K. L. Hansen:** It has been clearly brought out in the paper that the splitting of the end rings in the manner suggested has certain detrimental effects on the operation of the motor when running at its normal load and speed. For that reason it has apparently been very little used. Nevertheless it may at times be the means of overcoming some specific difficulty, and it therefore becomes very desirable for a designing engineer to know just what can be expected in the way of remedying the trouble, as well as the detrimental effects that are likely to result from the application of this method. I feel, therefore, that the author deserves credit for analyzing this problem.

With regard to the method used in the paper of arriving at the resistance of the end rings, perhaps, some might prefer to use shorter and more direct methods. For example, it can be seen at once from Fig. 4 in the paper that the maximum current in the ring at Section D is the sum of the average current in the rotor bars over one-half the pole pitch. Using Mr. Weichsel's notation of $\bar{I}$ to denote the maximum current in the rotor bars, the average current then is $\frac{2\,\bar{I}}{\pi}$. If $Z$ be the number of bars over one pole pitch, the maximum current in the end ring will then be $\frac{Z\,\bar{I}}{\pi}$. From this it follows that the effective current in the end ring is $\frac{Z\,\bar{I}}{\sqrt{2}\,\pi}$. Squaring this and multiplying by $\frac{R}{2}$, this being the resistance spanning one pole pitch, we have $\frac{R\,Z^2\,\bar{I}^2}{4\,\pi^2}$ as the losses per pole in one ring, which is identical with the result arrived at in the paper.

In the same way inspection of Fig. 6 of the paper will show that the maximum current in the ring in this case is equal to the sum of the average current in the rotor bars taken over one whole pole pitch, or twice as high as with the distribution shown in Fig. 4. It will also be seen that at any given instant the current in the end ring is always in the same direction. The current distribution in the end ring in this case varies sinusoidally from zero to a maximum value equal to twice that of the previous case, and hence can be expressed by

$$\frac{Z\,\bar{I}}{\pi} - \frac{Z\,\bar{I}}{\pi}\cos\beta$$

where $\beta$ is the angle in electrical degrees measured along the end ring with the section $G$ taken as reference. This current is seen to consist of two components, the first one being constant and having an effective value, $\frac{Z\,\bar{I}}{\pi}$, the second one varying sinusoidally and having an effective value, $\frac{Z\,\bar{I}}{\sqrt{2}\,\pi}$. The loss due to this current distribution is the sum of the losses of these two components and the loss per pole in one ring is, therefore,

$$\left(\frac{Z^2\,\bar{I}^2}{\pi^2} + \frac{Z^2\,\bar{I}^2}{2\,\pi^2}\right)\frac{R}{2} = \frac{3\,R\,Z^2\,\bar{I}^2}{4\,\pi^2}$$

which is seen to be three times as high as the losses corresponding to the current distribution shown in Fig. 4.

That the losses in the end ring due to "ampere-conductor set No. 1" and those due to "ampere-conductor set No. 2" can be considered separately may also be briefly shown by a similar line of reasoning. However, to some these shorter methods may not seem sufficiently conclusive, in which case they have recourse to the more detailed methods used by Mr. Weichsel in his paper.

It has then been shown that with the end rings split as suggested the rotor may be considered as being made up of two distinct circuits displaced 90 electrical deg. from one another and one circuit having an end-ring resistance three times as high as the other. In other words, the case is exactly equivalent to a slip-ring motor with two-phase rotor and unequal resistances in the two phases. If $I_1$ be the current flowing in the circuit of low resistance and $I_2$ the current flowing in the high-resistance circuit, the magnetizing force of the combined rotor currents can be shown to consist of two components, a forwardly rotating component equal to $\frac{\bar{I}_1 + \bar{I}_2}{2}$ and a backwardly rotating component equal to $\frac{\bar{I}_1 - \bar{I}_2}{2}$.

This backwardly rotating component of rotor m. m. f. rotates on the rotor at a speed corresponding to slip frequency, but as the rotor is slipping behind the main rotating field at the same rate, it follows that the relative motion between the main field and the backwardly rotating magnetizing force must be equal to twice the slip. As the poles of this magnetizing force pass the poles of the main rotating field of the same and alternate polarities, a pulsating torque is developed, the rate of pulsations being equal to twice the slip frequency. The amplitude of this torque pulsation is proportional to the product of the main field and the backwardly rotating component of the rotor m. m. f. It is responsible for the pulsations in the speed and line current discussed by Mr. Weichsel.

Besides being responsible for the speed and torque pulsations, this backwardly rotating component of the secondary magnetic field, causes some other interesting phenomena that have not been brought out in the paper. The average value of the torque pulsations is zero and the speed-torque curve is not affected by them. This curve may, nevertheless, be greatly modified by the backwardly rotating component of the secondary field. This can, perhaps, be best observed by taking an extreme case of unbalancing of the rotor circuits, that is by opening one of these circuits entirely and running the machine with single-phase rotor. In that case the backwardly rotating component of secondary m. m. f. is equal to the forwardly rotating component.

The backwardly rotating component of rotor m. m. f. produces a magnetic field of greater or less intensity, which generates a current in the primary of frequency $(2\,s - 1)$ times the line frequency, where $s$ is the slip. The voltage generated in the primary winding being proportional to the frequency, becomes equal to zero at half speed.

The intensity of the backwardly rotating field depends on the strength of the m. m. f. producing it and on the reaction of the current produced by it in the primary circuits. As there is no current generated in the primary by this field at half speed, it reaches its maximum intensity at this point and would reach very high values if it were not limited by saturation. The fact that saturation enters in and greatly modifies the mutual inductance between primary and secondary windings near the half-speed point makes the torque developed by the backwardly rotating field somewhat difficult to calculate in this region.

However, as soon as the speed departs, even slightly, from the half-speed point, currents will flow in the primary which by their damping action reduce the field strength below the saturation point. Under these conditions it can readily be seen that if $I_1$ be the secondary current in terms of the primary, the current generated by the backwardly rotating field is

$$I_0{}^1 = I_1 \left[ \frac{(2s-1)\,X_m}{r_0 + j(2s-1)\,(X_m + x_0)} \right]$$

where $X_m$ is the mutual reactance at full frequency, $r_o$ the primary resistance, and $x_o$ the primary reactance. The primary resistance loss resulting from this current divided by $(2s - 1)$ gives the torque (synchronous watts) developed by the backwardly rotating field at any speed. Below half speed this torque component is in the same direction as the motor torque, at half speed it becomes zero, and above half speed there is a generator action and it is in opposition to the main motor torque. For example, in Fig. 1 herewith is shown the speed-torque curve of a motor operating on single-phase secondary and having approximately the same constants as the motor used for illustration in Mr. Weichsel's paper. Curve *a* is the torque curve with balanced polyphase secondary. Curve *b* is the torque developed by the forwardly rotating field when operating with single-phase secondary, and curve *c* is the torque developed by the backwardly rotating component. The resultant of the last two, curve *d*, is the actual speed-torque under this condition.

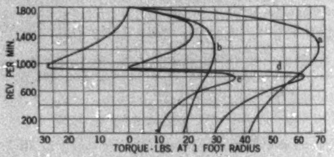

FIG. 1

It will be noticed that the resultant torque is zero at half speed, and if started from standstill the motor will not accelerate past this point unless external means are employed. Whether or not a motor will in general stick at half speed when operating on single-phase secondary depends on the secondary resistance. Is this is relatively high the motor may come up to full speed.

It should also be observed that the torque pulsations are most prevalent when the damping effects of the currents induced in the primary reduce the intensity of the backwardly rotating field to a low value, as for example near synchronism. When this damping effect is small, so that the backwardly rotating field approaches the forwardly rotating field in intensity, as for example near the half-speed point, the torque pulsations disappear.

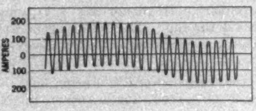

FIG. 2

A number of interesting points about a motor operating under this condition have been brought out by Gazda in a paper *Performance of Polyphase Induction Motors under Unbalanced Secondary Conditions*, (A. I. E. E. TRANS., Vol. XXXVI, 1917, p. 339). An oscillogram in that paper of the primary current taken with a rotor running at half speed plainly shows the low-frequency component generated by the backwardly rotating field of the rotor. It does not show any evidence of torque pulsations causing variations in the amplitude of the primary current similar to those indicated in the oscillogram shown by Mr. Weichsel which was taken with the motor running near synchronism. Fig. 2 herewith shows part of the oscillogram reproduced from Mr. Gazda's paper.

Fig. 3 herewith shows three speed-torque curves, also reproduced from the same paper, taken on a 50-hp., 60-cycle, six-pole motor. Curve No. 1 was taken with all three phases of the rotor short-circuited, curve No. 2 with balanced resistances in the three rotor circuits, and curve No. 3 was taken with single-phase secondary. It is interesting to note that the falling off of speed with increasing load is smaller when the machine is operating at half speed on single-phase secondary than when operating near synchronism with all the rotor phases short-circuited.

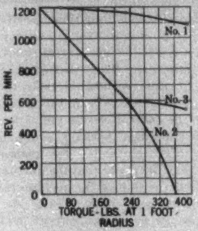

FIG. 3

Returning now to the case of a rotor with split end rings, or unbalanced rotor resistances, it is evident that the phenomena of single-phase rotor operation enter in, only, of course, to a much less marked degree. The current generated in the primary can in that case be approximately expressed by the following formula

$$I_o{}^1 = \frac{I_1 - I_2}{2} \left[ \frac{(2s-1)\,X_m}{r_o + j(2s-1)\,(X_m + x_o)} \right]$$

Fig. 4 herewith shows how the speed-torque curve would be modified on a motor similar to that discussed by Mr. Weichsel. Below half speed the torque will in general be increased so that the accelerating torque in that range is greater. At half speed there is a dent in the speed-torque curve and above half speed the torque will be considerably less than with normal operation. The detrimental effects are, therefore, as pointed out in the paper, reduced speed at full load, reduction in maximum power output, and reduced maximum torque in the upper stable range of the speed-torque curve.

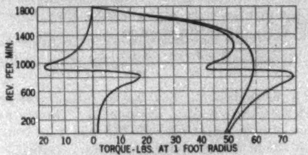

FIG. 4

The starting torque, it appears, may be increased or slightly reduced. Even when the starting torque is reduced, which would seem to be rather the exceptional case, the accelerating torque in the range from standstill to half speed is in general increased. This may in some instances be helpful in overcoming trouble due to sub-synchronous speeds, and the scheme has occasionally been used for this purpose.

The following figures given me by Mr. Oesterlein will show the locked readings on a motor on which the end rings had been split to overcome trouble due to sub-synchronous speed.

Before splitting the end rings—438 volts, 5.4 amp., 3.32 kw., 81 per cent power factor, 10.7 ft-lb. torque.

After splitting the end rings—440 volts, 4.25 amp., 2.53 kw., 77.5 per cent power factor, 12.25 ft-lb. torque.

In addition to showing a higher starting torque after splitting the end rings, the motor accelerated its load much more rapidly than when solid end rings were used.

Mr. Weichsel mentions only one beneficial effect from splitting the end rings, namely that of better starting torque per ampere. I believe we would be justified in adding one more, that of better accelerating torque.

**J. L. Hamilton:** As Mr. Weichsel has pointed out, the results of tests and analysis on squirrel-cage motors with split-end-ring rotors give, as one would expect, the effect of a high-resistance rotor.

His curves and data show lower maximum torque, lower maximum horsepower, and higher static torque per ampere for the rotor with split end rings.

The data show the magnetizing current with split end rings as being about 8 per cent higher than for solid end rings. One would expect the magnetizing current to be substantially the same.

Mr. Hansen in his discussion of this paper has very well pointed out the tendency for sub-synchronous load torque points when rotors with split end rings are used.

On account of the heavy static and pull-in torque requirements for induction motors, along with a minimum of starting current, it is necessary for the designer to avoid low-torque points very carefully. A designer, therefore, would be very careful in employing split-end-ring rotors in general-purpose motors. Central-station engineers are very desirous of keeping static and starting currents of motors to a minimum and would not look with favor, of course, on a motor with low-torque points, since this would mean large starting current per unit of starting torque.

**P. L. Alger:** (by letter) I think the general conclusions we may draw from this paper are, first, that any dissymmetry of the rotor design introduces so much extra reactance as to be distinctly harmful, and, second, that any dissymmetry in the rotor causes double-slip-frequency pulsations of torque and of line current. Practically all single-phase motors have a distinct double slip frequency "beat" in the noise they produce. It is probable that this beating is due to rotor dissymmetries.

It has often occurred to me that any dissymmetries in the rotor, or the use of high-impedance end rings, may cause cross currents to flow between squirrel-cage bars through the rotor punchings, and that these currents may account for various secondary phenomena, such as extra losses. Early induction motors were nearly all provided with insulated squirrel-cage bars, and this practise is still followed by many European manufacturers, the idea being presumably to avoid the possible detrimental effects of such cross currents between bars.

I should like to inquire whether Mr. Weichsel has had any experience indicating that these currents are of appreciable magnitude. I should think that they would be sufficiently large with a split-end-ring construction to affect materially the motor performance.

**W. L. Upson:** I think that we might find, one of these days, when we go over this paper from another point of view, that we might want to extend the investigation and exaggerate the very defects that are outlined here. For example, some use might come of exaggerating the pulsations in connection with induction generators, or perhaps if we made some other splits in the rings, differing from the 90-deg. splits that the author has mentioned. I therefore want to put in this thought, that we have here an extension of our knowledge that later on may be of direct value to us.

**B. T. McCormick:** Mr. Hansen has suggested a "short-cut" method of obtaining the effective resistance of a squirrel-cage rotor, which is similar to the method which I have always used. However, I have never had occasion to determine the resistance of a split-ring squirrel-cage rotor, either by the method suggested by Mr. Hansen or by any other method.

Mr. Hanson calls attention to the tendency of this motor to partake in some degree of the peculiarities of a motor with a single-phase rotor, and its probable tendency to hang at half speed. Mr. Weichsel did not make any experiments on this motor to determine its torque at intermediate speeds, and I am inclined to agree with Mr. Hansen that this motor might have some tendency to hang at half speed, but whether slight or decidedly marked, I cannot say.

Mr. Hansen also remarked that the leakage reactance of this motor is the same as that of a normal motor and that the greater leakage reactance mentioned in Mr. Weichsel's paper is really not such, but merely an effect due to the presence of a backward rotating component. This is merely another way of describing the same action. It is usually easier to combine all the various actions and express their effect as one net result, and the best method of stating the present action is to say that the machine, when tested, gives a circle of smaller diameter than the standard motor, which means that in effect it has a greater leakage reactance.

Mr. Alger asked regarding the effect due to stray currents brought about by not having insulated rotor bars. No investigation along this line has been conducted. I can easily imagine that there would be a tendency for the currents to stray from their proper paths in the squirrel-cage winding in an endeavor to find short cuts through the iron, to follow as closely as possible the natural symmetrical current distribution of the standard squirrel-cage construction. Some effect of this kind probably takes place, and if one were to build two split-ring squirrel-cage rotors, one with uninsulated bars and another with insulated bars, it would not be surprising to find that these rotors when tested show somewhat different performances.

There is one other point that I am rather surprised has not been mentioned by someone, and that is the difficult problem of bracing the split rings to withstand the action of centrifugal force, especially at high speeds. This, I think, is one of the most important criticisms against this type of rotor.

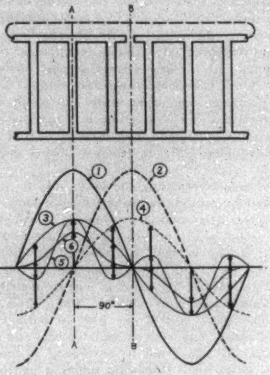
**R. E. Hellmund:** (communicated after adjournment) In the beginning of the paper by Mr. Weichsel, the assumption is made that the currents in the squirrel-cage bars are distributed according to a sine curve (see Figs. 2, 4, and 6). This assumption is not quite correct, as is shown in the accompanying Figs. 5 and 6.

In order to simplify the matter as much as possible, a two-pole rotor with three squirrel-cage bars per pole has been assumed. Under the assumption of a sinusoidal primary field, the voltages in the squirrel-cage bars can be assumed to follow a sinusoidal curve. The currents flowing in the bars have then been calculated by a simple application of Kirchhoff's laws, first assuming that all the resistance is in the bars; secondly, that all the resistance is in the rings; and thirdly, that the resistance is equally distributed between the bars and the rings. The results of this calculation are shown in Fig. 6. It will be seen that while the currents correspond to a sine curve in the axis $(B\ B)$, such is not the case in the axis $(A\ A)$ except in the case where all the resistance is in the bars.

These data are not given primarily to indicate that the results derived in the paper depart materially from actual facts. This I have not checked in detail, and I believe that unless the resistance of the end rings is a very material part of the total, most of the conclusions given in the paper are essentially in line with facts. The principal reason for showing the attached Fig. 6 is that it permits the bringing out of a number of points not touched upon in the paper.

The figure shows that with currents as actually flowing under different conditions, the rotor m. m. f. is different in the two axes at right angles to each other and that such difference is influenced by the percentage of the total resistance put into the end rings. This feature of the secondary m. m. f. is the same condition as would be obtained, for instance, in a two-phase wound secondary having different resistances in the two phases. In other words, the splitting of the end rings brings about conditions which are equivalent to an unbalanced wound secondary. This being the case, a number of facts can be derived which have been fully appreciated for some time in connection with unbalanced wound secondaries.

An extreme example of unbalanced wound secondary is a single-phase secondary. This case has been described in a very simple manner by B. G. Lamme in an article in the *Electric Journal* of September, 1915. Fig. 7 given here is reproduced from this article.



FIGS. 5 AND 6.

1. Bar voltages at one instant of time
2. Bar voltages 90 deg. later
3 and 4. Bar currents, all resistance in bars
5 and 4. Bar currents, all resistance in end-rings
6 and 4. Bar currents, resistance equally divided between bars and end-rings

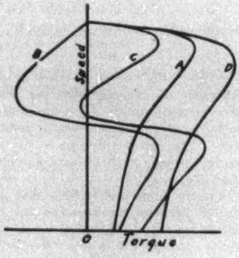


FIG. 7

It will be recalled that the resultant speed-torque curve $C$ of the motor with single-phase secondary is the sum of two component curves $A$ and $B$; curve $D$ represents the same motor with polyphase secondary. If the secondary is not single-phase but merely unbalanced polyphase, the same conditions apply qualitatively, but to a lesser degree quantitatively. In other words, the curve $C$ will not actually indicate negative values above one-half synchronous speed, but there will merely be low torque points, or what are commonly called "cusps," in the speed-torque curve.

It follows from the above that the same conditions may be expected with the slotted-end-ring squirrel-cage construction. It also seems that the increased apparent leakage mentioned in the paper, resulting in starting torque smaller than expected, may be explained partly by the character of the speed-torque curve with unbalanced secondary (see Fig. 7). Furthermore, since the field form of the rotor in axis ($A$ $A$) is materially different from that of the stator, appreciable differential or belt leakage has to be expected. Finally, there is some increased leakage around the end rings.

Fluctuations in primary current of twice slip frequency, as found by Mr. Weichsel, are also obtained in motors having unbalanced secondary phases. This effect, which again can best be demonstrated by reference to the extreme case, namely, a single-phase rotor, may be explained as follows: Consider the rotor running with a low slip. The single-phase currents in the rotor set up a pulsating field, which may be resolved into two fields rotating in opposite directions at a speed, relative to the rotor, corresponding to slip frequency. These two fields induce voltages in the primary of two different frequencies. One field rotates in the same direction as the rotor, adding the slip-frequency speed to the mechanical speed to induce a voltage of line frequency in the stator. The other field, rotating against the rotor, subtracts the slip-frequency speed from the mechanical speed $(1 - S)$, inducing in the stator a voltage of a frequency equal to the line frequency minus *twice* slip frequency. Thus, two voltages, differing from each other by twice slip frequency, are induced in the primary. In general, two voltages of nearly the same frequency acting on the same circuit produce variations, or "beats," in the current of a frequency equal to the difference in the two frequencies. In our case of a polyphase induction motor with single-phase or unbalanced secondaries, this "beat" frequency is twice the slip frequency, as explained above. These beats may or may not have a disturbing influence of practical importance on the line voltage. It is to be expected that in the majority of cases the influence is not of practical importance because wound-secondary motors are frequently operated with unbalanced secondaries without causing much disturbance.

Finally, attention may be called to the fact that the circle diagram does not give entirely correct results with unbalanced secondary, and therefore not with the cut end-ring construction either. The greater the unbalance of the secondary, the greater the discrepancy will be, and in the case under consideration it would appear that the greater the proportion of resistance in the end rings to the total rotor resistance, the greater the discrepancy should be. Referring once more to Fig. 6, it will be seen that the extreme case having all resistance in the end rings has very marked higher harmonics (see curve 5, for instance). It is not unlikely that such a condition may also bring about low-torque points, or cusps, at points other than the one above one-half synchronous speed.

**G. L. Hoard:** (by letter) This paper will not receive the attention which its excellence merits because the results of the investigation described are negative, that is, negative in the sense that the possibilities of the motor investigated are not very promising. This does not lessen the value of the paper, however. It is quite as important to know the limitations of a particular apparatus as to know its possibilities. The author is to be congratulated on the clear, concise manner in which the subject is presented.

As for the motor itself, it seems to give little promise in the way of improvement in induction-motor characteristics. Its only advantage apparently is an increased torque per ampere, but this advantage is much more than offset by the disadvantages of lower starting torque, lower breakdown torque, and lower maximum output. There is also one other possible disadvantage which is not mentioned in the paper. The heating in the rings is not uniform. The loss at section A of ring 2 in Fig. 6 will be considerably larger than at points near the cut in the ring. This is not likely to be a serious objection in a rotor structure, having the high thermal conductivity and good ventilation characteristics possessed by the squirrel cage. It would be objectionable, however, in any form of wound rotor. I should like to ask if there was any evidence of local heating in any of the tests run on the experimental motors?

**H. Weichsel:** Mr. Hoard pointed out that the heating in different sections of the rings must be different. This statement is correct. The current distribution in the different sections of the ring, determined by the method outlined in my paper, when plotted against time, is given in Fig. 8. It will be seen from the figure that the maximum heating occurs in the section A of Fig. 6 of my paper. Unfortunately, during the tests, no attention was paid to this phenomenon, which no doubt must exist.

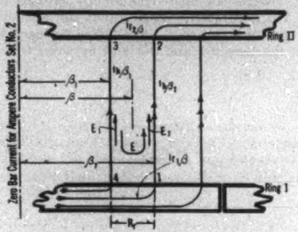

FIG. 8

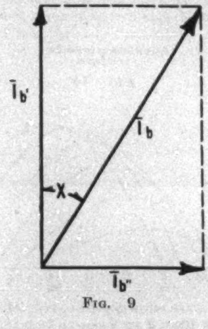

FIG. 9

In the discussion, references were made to the effect of non-insulated rotor bars. My experience has shown that in larger machines, even when a standard squirrel cage is used, quite appreciable currents flow during the starting period from the rotor bars into the laminations when the bars are not insulated. I know of instances where during the starting period very noticeable sparks occurred between the bars and the laminations. The heavy starting currents set the bars into vibration and, therefore, the contact between laminations and bar varied rapidly, and this resulted in quite visible sparks. If this condition exists in a standard squirrel cage, there is no doubt that the same condition exists in a much more pronounced manner in a squirrel cage with split rings.

Different discussors also have pointed out the similarity between a squirrel-cage rotor with split rings and a wire-wound armature with unbalanced resistance in the rotor. This similarity is correct. The tendency to a saddle formation in the speed-torque curve as pointed out by subsequent discussors doubtless exists in the machine with split rings in the same manner as in a machine with wire-wound armatures and unbalanced rotor resistances.

Mr. Hellmund referred to a point which is theoretically of greatest importance. He pointed out that the solution offered in my paper is based on the assumption that the current distribution in the bars follows a sine wave and that there is a possibility that this is not the distribution which actually exists in the bars.

In order to obtain an inside view of the actual distribution of currents in the bars, he applied the Kirchoff laws to a squirrel cage having only three bars per pole and determined for this structure the current distribution in the rings and the bars under the assumption that the e. m. fs. generated in the bars are of sine-shape distribution. This method of attack is perfectly correct, but I believe that the results obtained in this manner should not be generalized and applied to that problem of my paper, which deals with the current distribution in the squirrel-cage rotor having an infinite number of bars and split resistance rings.

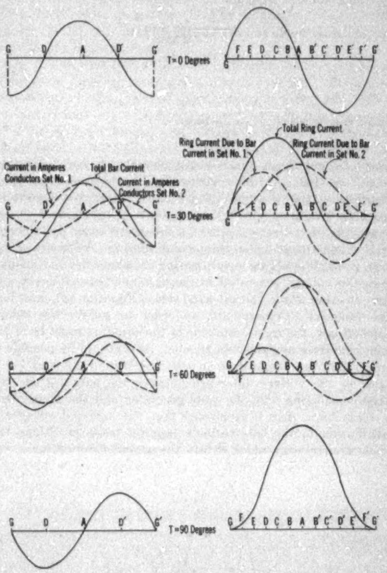

FIG. 10—BAR CURRENTS AND RING 2 CURRENTS

There is no doubt that the voltage generated in the bars due to the relative movement of the bars against a sine-shape rotating field must have a sine-shape distribution in space.

In my paper the first Kirchoff law, that the sum of all currents must be zero, has been fulfilled, as the whole problem was attacked by determining the ring currents by adding all the bar currents which flow into the ring.

Therefore, if it should be possible to prove that with the current distribution obtained in this manner, the voltage distribution along the bars and rings is such as to satisfy the second Kirchoff law, that is, "the sum of all voltages must be zero," it is evident that the assumed current distribution in the bars and the distribution in the rings as set forth in the paper is the actual distribution.

Let us consider a section of the squirrel cage as shown in Fig. 8 herewith. The distribution of the resultant current in the rings and bars is shown by arrows in agreement with the distribution found in my paper. For the local circuits, 1-2-3-4, we can write the second Kirchoff law in the following form:

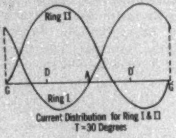

FIG. 11

$$E_2 - E_1 = E = i_{b_{\beta_2}} \cdot r_b - i_{b_{\beta_1}} \cdot r_b - i_{r_{2\beta}} \cdot R_r + i_{r_{1\beta}} \cdot R_r \quad (1)$$

which can be rewritten in the form:

$$(E_2 - E_1) - r_b\,(i_{b_{\beta_2}} - i_{b_{\beta_1}}) = R_r \left\{ i_{r_{1\beta}} - i_{r_{1\beta}} \right\} \quad (2)$$

where $E_1$ and $E_2$ are the voltages generated in bar 3-4, respectively bar 1-2. As the rotating field has a sine-shape space distribution, the voltages $E_2$ and $E_1$ must also have a sine-shaped space distribution. According to the assumption made in my paper, the bar currents, $i_b$, have a sine-shape space distribution. It is evident that under these conditions the difference of the e. m. f. which is left when subtracting the ohmic drop in the bars from the voltage generated in the bars must also follow a sine law—in other words, the left-hand side of Equation (2), must be a sine function. Consequently in order to satisfy the second Kirchoff law, the right-hand side of the equation must be of the same character as the left-hand side. If it should be possible to prove that the ohmic drop in the ring section 2-3 and 1-4 is equal to the voltage difference between the bars 1-2 and 3-4 when considering only the volts generated and the ohmic drop in these bars, then it is proved that the assumed sine-shape distribution in the bars actually requires potentials along the whole squirrel cage which satisfy the second Kirchoff laws.

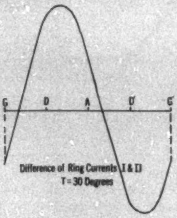

FIG. 12

If the bar current distribution in ampere conductor set No. 1 of the original paper follows a sine law as per:

$$i_{b_{\beta}}' = I_b' \cdot \cos\beta \quad (3)$$

where angle $\beta$ is measured from the point $G$ in Fig. 4 in the paper, then the ampere distribution in the ampere conductor set No. 2 follows the equation:

$$i_{b_{\beta}}'' = I_b'' \cdot \sin\beta \quad (4)$$

The resultant ampere distribution in the bars is given by equation:

$$i_b = I_b' \cos\beta + I_b'' \sin\beta \quad (5)$$

But the maximum bar currents $I_b'$ $x$ $I_b''$ for set No. 1, set No. 2, respectively are related to the maximum resultant bar current $I_b$ by equations:

$$I_b' = I_b \cos x \quad (6)$$

$$I_b'' = I_b \sin x \quad (7)$$

These two equations, (6) and (7), follow directly from the diagram Fig. 9 herewith, where $X$ is the time displacement of the resultant ampere conductors against the axis 0-1, which represents the time when the ampere conductors of set No. 1 are a maximum and set No. 2 are zero. Substituting (6) and (7) into (5), the resultant bar current is found to be:

$$i_{b_\beta} = I_b\,(\cos x \cos\beta + \sin x \sin\beta) \quad (8)$$

The same general law holds true for the voltages generated in the bars. The generated voltage minus the ohmic drop in the bars gives the "free voltage." This "free voltage" between the ends 2-3 of the bars 2-1 and 3-4 and between the ends 1-4 of the same bars must be equal to the ohmic drop appearing across these points due to the ring currents. As the bar currents as well as the generated bar voltages follow the same law, the "free voltage" which appears across the points 1-2 and 3-4 can be considered as the differential of Equation (8) when the latter is multiplied with a constant taking care of the ohmic drop. The potential difference referred to above is, therefore, given by:

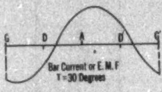

FIG. 13

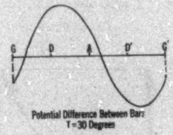

FIG. 14

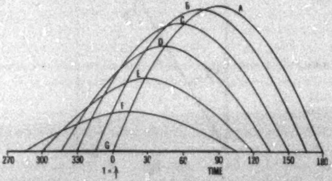

FIG. 15—CURVES SHOWING RELATIVE MAGNITUDES OF CURRENTS IN RING 2 AT VARIOUS INSTANCES OF TIME

$$d\,E = K\,(\sin x \cos\beta - \cos x \sin\beta)\,d\beta \quad (9)$$

The current flowing in ring No. 2 due to ampere-conductor set No. 1 is:

$$i_{r_{2\beta}}' = I_b \cos x \left( \frac{Z}{\tau} \right) \sin\beta \quad (10)$$

which follows from Equation (3) of the paper and Equation (6) of this discussion.

In the same manner the current in ring 2 due to ampere-conductor set 2 follows from Equation (**16**) of the paper and Equation (**7**) of the discussion:

$$i_{r_{2\beta}}'' = I_b \, . \, \frac{Z}{\pi} \sin x \, (1 - \cos \beta) \tag{11}$$

The resultant current in ring 2 is the sum of (**10**) and (**11**) and is given by:

$$i_{r_{2\beta}} = I_b \frac{Z}{\pi} \left\{ \sin x \, (1 - \cos \beta) + \cos x \sin \beta \right\} \tag{12}$$

In the same manner the resultant current in ring 1 is found to be:

$$i_{r_{1\beta}} = I_b \, . \, \frac{Z}{\pi} \left\{ \sin x \, (1 + \cos \beta) - \cos x \sin \beta \right\} \tag{13}$$

The difference between these currents gives:

$$i_{r_\beta} = 2 \, I_b \, . \, \frac{Z}{\pi} \left\{ \sin x \cos \beta - \cos x \sin \beta \right\} \tag{14}$$

This current multiplied by the ohmic resistance $R \, . \, d\beta$ for the infinitely small length of the ring coverd by an angle $d\beta$ gives Equation (**15**) for the ohmic drop in the rings over a section located at point $\beta$, that is, the ohmic drop of ring sections 2-3 and 1-4 of the rings 1 and 2.

$$= 2 \frac{Z}{\pi} I_b \left\{ \sin x \cos \beta - \cos x \sin \beta \right\} d\beta \tag{15}$$

It will be seen that this is exactly the same law as Equation (**9**), which represents the potential differences of points 2-3 and 1-4 due to the difference of generated voltage minus the ohmic drop for bars 1-2 and 3-4. Consequently the second Kirchoff law has been satisfied,—the sum of all the e. m. f. in the circuits 1-2 and 3-4 is zero. It has, therefore, been shown that for an infinite number of bars the assumption made in my paper of sine-shape current distribution in the bars is correct provided the rotating magnetic field has sine-shape distribution in space.

If, however, the number of bars becomes very small, then, as Mr. Hellmund has shown, the distribution of currents no longer follows a sine law. Experience with standard squirrel-cage rotors has shown that relations derived for an infinite number of bars give results close enough to be applied to a standard squirrel cage having a number of bars such as is usually found in practise, that is, approximately 10 or more bars per pole. It is justifiable to conclude that similar relations exist for squirrel cages with split rings.

The following is a brief description of a graphical solution:

Fig. 10 herewith shows for the time intervals $t = 0$, $t = 30$, $t = 60$, $t = 90$, the current distribution as determined in my paper for the bars and ring No. 2.

Fig. 11 herewith shows the current distribution as determined in my paper for rings 1 and 2 at a time $t = 30$ deg. The difference between these current distributions is given in Fig. 12 herewith, which is a sine-shaped curve and is 90 deg. displaced from the assumed current and voltage distribution of the bars shown by Fig. 13 herewith. But the potential difference between the ends of the bars due to the generated voltages and ohmic drop in the bars is the differential of curve Fig. 13 and follows a sine function as per Fig. 14, which is 90 deg. displaced against curve Fig. 13. Consequently it is co-phasal with the curve of Fig. 12. It follows that this graphical method leads to the same results found above by mathematics, that is, the current distribution as found in my paper for an infinitely large number of bars satisfies the Kirchoff laws.

# Excitation Systems
## Their Influence on Short Circuits and Maximum Power

BY R. E. DOHERTY*
Member, A. I. E. E.

*Synopsis.—Since 1920, when the general subject of excitation systems was reviewed at the White Sulphur Springs Convention, two important problems regarding these systems have arisen: One relates to the required excitation characteristics during system disturbances, and the other to the characteristics which are necessary in order to increase the maximum power above the steady state or static limit—i. e., in order to operate the synchronous machines under the condition of dynamic stability.*

*With respect to the former problem, the advantages and disadvantages of quick response excitation are considered. Such excitation tends, of course, to hold up the voltage during system disturbances, and is thus advantageous. However, it also increases the short-circuit current which circuit breakers must interrupt. The general trend in installing such systems is, therefore, in the direction of requiring larger circuit breakers. Such an excitation system is justified in many cases, and, indeed, it is essential in some. The extent to which the quickness of response and the maximum value of the excitation voltage are carried, is a question which, at present, should be settled by the conditions of the particular case.*

*As to increasing power limits, results are given which are very promising with respect not only to long distance transmission, but also to power systems which have approached the power limit as determined by the condition of present normal operation. A new regulator, unique in its operating characteristic, has been developed which makes it possible to sustain stable operation under the condition of dynamic stability, thus increasing the maximum power by taking advantage of a heretofore unexploited range of operation of synchronous machines. Comparative test results are given for different types of regulators. The new regulator alone showed extraordinary gain, giving an increase of maximum power from a steady state (steady-field excitation) value of 110 kw., to a maximum of 415 kw., on a system comprising a synchronous generator supplying power directly to a synchronous motor. This shows the extent of improvement obtainable in the machines themselves.*

*With an artificial 500-mile straightaway transmission line between the machines, a maximum power (received at the motor) equal to 90 per cent of the "infinite bus" value was obtained. The infinite bus value was 61 kw., 55 kw. was obtained, 44 kw. being the steady state power limit.*

*The excitation system, as controlled by the new regulator, provides a component of excitation voltage which is at all instants equal to the i r drop in the field circuit during the necessary small oscillation under dynamic stability. The i r drop is therefore compensated, the characteristic of the regulator being to introduce the effect of negative resistance. And with zero effective field resistance, the maximum power corresponds to the condition of constant flux linkages—the power under that condition is greatly increased above the constant field current value. This condition is approached by the new regulator.*

* * * * *

### INTRODUCTION

THE subject of excitation systems was reviewed comprehensively by several authors at the Summer Convention in 1920.[1–6] Interest has been renewed in this subject in the last few years by the new problems which have arisen in connection with power transmission. Two predominating facts have changed profoundly the general aspect of power transmission: One is the rapidly rising demand for increased reliability of service, and the other, the radical increase in the load per transmission circuit and in the specific loading of synchronous machines. And these facts have given rise to two corresponding problems in excitation systems. One related to the quick and adequate application of excitation voltage under the condition of sudden disturbances, such as short circuits, in order to reduce to a minimum the drop in line voltage—thus preventing to the greatest practicable extent the loss of load either from relay operation or from actual breakdown of motors or synchronous machines. The other relates to the possibility of increasing the maximum power above the generally recognized steady state or "static" limit—by operation under *dynamic* stability, that is, stability which depends upon motion. Instances: A spinning top, a staff balanced by a juggler, a bicycle in motion. Any tendency to fall gives rise to restoring forces. These may be inherent, as in the case of the top, or may be impressed by an external agency, as in the case of the staff or a slowly moving bicycle. But in either case the tendency to fall initiates the restoration. Moreover, in dynamic stability the play of these opposing forces is continuous. In the case of the synchronous machine operating under the condition of dynamic stability, the tendency to fall out of step initiates, through the voltage regulator, an appropriate change in excitation, thus providing the restoring forces. It is the purpose to discuss these two problems, and to report certain facts which appear to be steps forward in the solution.

Although the two problems are discussed separately, since in certain fundamental respects they are quite distinct, they are nevertheless related in the important respect that the problem of preserving continuity of service through periods of system disturbance would always be present, regardless of whether the system were normally operating under *static* stability or *dynamic* stability. However, it should be thoroughly appreciated that these two states of operation are fundamentally different, and that excitation systems which are satisfactory for the one may be altogether inadequate for the other.

*Presented at the A. I. E. E. Regional Meeting, St. Louis, Mo., March 7-9, 1928.*

With reference to the earlier work on excitation systems in connection with power transmission, two possible means for obtaining improved control of the excitation were suggested by the author at the Seattle Convention in 1925.[7] One was the use of a series exciter in the excitation circuit, in order to obtain immediate response in increased excitation voltage on the occasion of any sudden change in the electrical condition of the synchronous machine—in other words, to obtain an equivalent negative resistance in the field circuit. This, of course, would lengthen the duration of the transient, *i. e.*, tend to sustain the spontaneously increased alternator field current. The other suggestion was the use of a mercury arc rectifier as an adjunct in the excitation circuit. This would give immediate change in alternator field current in proportion to the change in armature current. Tests showed that with this scheme it was possible to operate above the steady state power limit. Further investigation has shown that there are equally effective and simpler means for both cases: One relates to the problem of short circuits, and the other to the problem of increasing the maximum power by operation under dynamic stability. These will now be considered.

## EXCITATION CONTROL DURING SYSTEM DISTURBANCES

The value of what has been termed "quick-response" or "high-speed" excitation, in connection with system disturbances, has been widely discussed.[8–12] There are, however, important points which warrant further emphasis. These relate to the rate of application of excitation, the maximum value of excitation voltage, the effect of this on short circuit currents, and also to the voltage regulator's role.

In the first place, what is quick-response excitation? When does the response of an exciter cease to be sluggish, and become quick? The term refers, of course, to exciters whose rates of magnetic build-up and build-down are higher than those ordinarily obtained with standard machines. The rates obtained with the latter over a wide range† are, say, from 15 or 20 volts per second to perhaps 250 volts per second in the case of 250 volt exciters, and half those values for 125 volt exciters, the range depending upon such factors as the volume (the $d^2 l$), and the speed of the exciter, saturation, character of the iron, etc. It would thus be somewhat venturesome to attempt to set a dividing line between high and low rates. However, anyone would probably agree that 25 volts per second is a low rate, and 1000 volts per second is a high rate. The width of the questionable zone depends, in the present state of definition, upon individual notions. But for the purpose of this discussion, we may very reasonably regard as quick-response excitation those cases where extraordinary means are employed to obtain rates of voltage change, both increase and decrease, unattainable in standard shunt or compound-wound exciters.

The extraordinary means referred to are, of course, familiar to all designing engineers, and include a number of schemes, such as special exciter design; the use of a series resistance in the shunt-field circuit, and impressing a correspondingly higher voltage; or, impressing a much higher voltage on the exciter field than corresponds, by Ohm's law, to the desired shunt-field current. Whether the latter, for instance, is accomplished by paralleling the field coils and impressing the given voltage, or by rewinding the coils for series connection, with the same amount of copper but with an appropriately smaller number of turns, and impressing the given voltage on the series circuit, the result is the same—namely, an accelerated voltage change. Such schemes for obtaining a high rate of d-c. voltage have been used for years,[13] ever since applications have been encountered which required a more rapid change in excitation voltage than could be obtained by standard machines. Quick-response excitation, as well as certain means of obtaining it, is not something which has recently come upon us as a new phenomenon.

Merely an additional application has arisen. If the line voltage drops, loaded motors may break down, the generators may fall out of step, and other disagreeable things may occur. If the drop in voltage takes place slowly, as occasioned, for instance, by a gradual application of load, the required rate of increase in excitation to prevent a critical dip in the voltage would be correspondingly low. However, if the drop is sudden—as produced by a partial short circuit—any possible advantage to be had from increasing the excitation voltage would be accomplished only by increasing it quickly. Thus, with the growth in the load per transmission circuit and, at the same time, a growing demand for greater reliability of service, it has become desirable and, in some cases, necessary to extend the use of quick-response excitation, formerly confined chiefly to special cases of industrial application in the field of large power transmission systems.

Published literature has brought out clearly the foregoing fact, that the quick application of excitation voltage on the occasion of a short circuit will decrease the chance of system breakdown—because it tends to hold the voltage up; but, as already mentioned, there are other important aspects of the subject which deserve further emphasis.

One of those aspects is that there are certain important details which are essential to an *effective* application of quick response excitation systems. The purpose being to reduce to a minimum the drop in voltage due to a sudden disturbance, it is clearly desirable for certain practical cases to have not merely a relatively rapid increase in excitation voltage, but the highest practicable rate and a relatively high value to which the excitation voltage can build up. For instance, a practical case of 250-volt normal excitation might require 5000 volts per second or higher, instead of 500, and a maximum value ("high ceiling") of say

---

†Data in this connection will be given in a forthcoming paper in the *General Electric Review* by Mr. H. W. Washburn.

1000 volts, instead of 300 or 400. These points have been discussed by Mr. D. M. Jones in a recent issue of the *General Electric Review*.[12]

There are thus special applications in which, for optimum results, these features must be given due consideration.

But such features can be carried too far. The consequent increase in short-circuit current may create equally difficult problems. Indeed, the purpose of quick response excitation may be stated in terms of short-circuit current. Thus, reducing the voltage drop during the period of short circuit to a minimum, is equivalent to increasing to a maximum the value of the short-circuit current which the circuit breaker must open. Until the last few years the problem had been to reduce the short circuit current, but now, in these instances at least, the tendency is to increase it. In many cases this would not entail difficult switching problems, but there are some in which it would. Therefore, the suggestion is offered that the general trend has reversed to the direction of sustaining high short-circuit currents; and that in addition to both the proposed shorter time interval between the short circuit and the opening of the switch, and the radical increases in the generator capacity connected to a single bus, this is heading toward difficult switching conditions. Thus in the application of such excitation systems this general trend should be considered in true perspective.

The voltage regulator's place in this picture should be mentioned. So far as the particular function is concerned (of reducing the voltage drop during short circuit to a minimum), the *foremost* requirement of the regulator is that it should close its contacts immediately after short circuit, and keep them closed until the maximum desired excitation voltage appears across the field-collector rings of the synchronous machine; though there are other requirements, naturally. This fact, it seems, is generally recognized; and such commercial regulators generally are available. There are, however, other very important regulator functions and required characteristics which do not appear to be generally understood, particularly in connection with the problem of dynamic stability. These will be discussed later on.

To sum up the more important points regarding the influence of the excitation system during system disturbances: Quick-response excitation is highly desirable from the standpoint of reducing to a minimum the voltage drop during short circuit; and to this end, much higher rates and much higher values of excitation voltage are required, in certain practical cases, than had formerly been considered in quick-response systems. The definite present trend, however, in installing quick-response excitation systems is in the direction of increasing the duty on circuit breakers; and as a question of broad policy this should be fully considered. With respect to the voltage regulator, its foremost requirement in connection with short circuits is that it should promptly close the contacts and keep them closed until the desired d-c. voltage across the field-collector rings has been attained. Regulators which will do this generally are available.

### EXCITATION CONTROL FOR DYNAMIC STABILITY

Formerly, voltage regulation, line loss, and short circuits were the chief limitations considered in power transmission systems. During recent years another limitation, maximum power, has become very important. Under economic pressure, the load per transmission circuit has been increased until the maximum power which it is possible to transmit under existing conditions and practise, has been approached; indeed, in certain proposed power developments it has been exceeded. This has occasioned active investigation to increase the maximum power above the steady state, or static power limit.

Experience and early study regarding the possibilities in the design of the synchronous machine showed that although a gain in maximum power could be made in this way, it was nevertheless a moderate one, considering the economic limitations involved and the subject sought.[7] Even if such gains were made available—as they have been—there would, nevertheless, still remain in these machines the latent possibilities of increased maximum power beyond the static limit. And, as early studies indicated, it was these possibilities which could be rendered available by a proper excitation system. This view was presented at Seattle[7] in 1925, together with evidence that operation beyond the static limit could be obtained by proper excitation control.

With this fact established, intensive investigations were made of various forms of excitation systems with the object of increasing the gain and simplifying the circuits. Analysis and tests have definitely established three very important points. One point is that the factors of mechanical inertia, electrical transients, and damping afford a sufficient time element to make it possible to *sustain* operation under *dynamic* stability far beyond the *static* power limit. As discussed later on, the possibilities in this connection proved to be much more favorable than earlier investigation has indicated. The second point is the very essential part which the voltage regulator plays in this accomplishment. Third, the relatively low rates of change of excitation voltage at which it is possible, with proper regulation, to sustain dynamic stability. Although quick-response excitation may be desirable for many reasons, it is nevertheless a fact that it is possible to sustain dynamic stability with ordinary exciters, using proper regulation. These aspects will now be discussed in detail.

Consider the general nature of the phenomenon in question. It is a familiar fact that when a synchronous motor is supplied with power from a synchronous generator, either from a common bus or through an intervening reactance, there is a definite maximum power in either case, which can be transmitted at normal voltage under steady field conditions. Beyond this limit, generally referred to as the steady state or static power limit, the machines break apart.

It is also a fact that considerably more power can be transmitted by the same machines, over the same circuits, provided that the field excitation of the machines, instead of being held steady, is properly varied in accordance with the demands from moment to moment. Under this condition, as explained in Mr. Nickle's paper, the machines are, at each moment, either actually drifting further apart in phase with a consequent drop in voltage, or nearer together in phase with a consequent rise in voltage. That is, with a constant shaft load under such conditions of operation, there are sets of critical values of terminal voltage, field excitation, and space phase position, at which the electrical power input is just sufficient to supply the motor losses and the mechanical load; and on either side of this critical and sensitive balance, the tendency, *if the system were left to itself with no impressed change in field excitation*, would be either to fall apart with decreasing voltage and decreasing useful power input, or to fall close in phase with increasing voltage and increasing power input. Under these conditions the system is inherently unstable. But with proper control of the impressed excitation voltage, dynamic stability can be maintained, and the maximum power thus increased.

Now it is a well-known fact that the alternator field current tends inherently to adjust itself to maintain constant magnetic linkages in the field circuit.[7] This tendency is greater, the lower the resistance of that circuit; and in the limit, if the resistance were zero, the linkages would thus be maintained absolutely constant. Stated in other words, with zero resistance in the field circuit the effect of armature reaction on the field would be completely compensated.

The purposes of the mercury arc and the series exciter schemes, already referred to, are fully discussed in the literature.[7] The former effects partial compensation by changing the alternator field current in proportion to the line current, the latter, by introducing a component of excitation voltage which is at all moments proportional to field current, thus being, in effect, a negative resistance. With proper characteristics it should be possible in this way to introduce a negative resistance equal to the positive (*i. e.*, ohmic) resistance, and thus obtain the beneficial effects of zero resistance as discussed above. Although the series exciter has this advantage, it has some disadvantage in that it introduces an inductance (the exciting inductance of the exciter) in the external field circuit, thus increasing the transient reactance of the alternator and, therefore, decreasing the maximum power. Moreover, it would involve a somewhat complicated control. So, although both the mercury arc and the series exciter may yet find application in this connection, this investigation has shown that means are available which now appear much more promising.

The effect of negative resistance in the alternator field can be obtained by a special vibrating type regulator, actuated from the a-c. line voltage, and controlling an ordinary exciter. The inherent relationships between displacement angle, line voltage, field current, etc., during the necessary oscillatory motion in dynamic stability, are such that a component of excitation voltage proportional to the varying field current can be impressed by the above means, provided the regulator has proper characteristics. The above relationships are roughly indicated in Fig. 1. The oscillations may not be periodic; and the magnitude of variations would normally be less than indicated. But some oscillation must nevertheless be present in dynamic stability. The problem is to obtain an excitation system which will apply a voltage as shown as curve *d* in Fig. 1, that is, one which is in time phase with, and proportional to, the variable field current. It would thus constitute in effect a negative resistance. If the excitation voltage in this way were made equal to the *i r* drop at all instants, the objective of equivalent zero resistance would be attained.

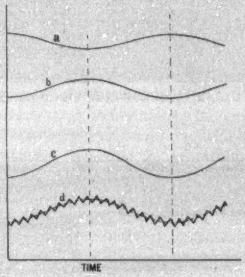

FIG. 1—PHASE RELATIONSHIPS DURING ANGULAR OSCILLATION OF AN ALTERNATOR

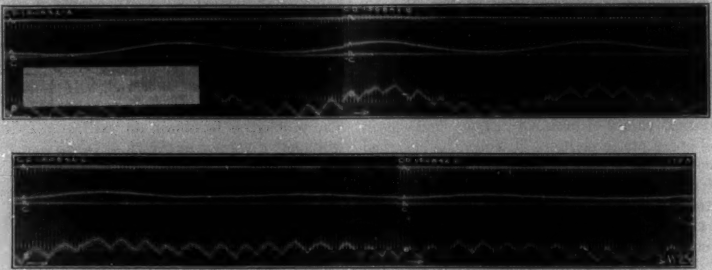
(a) Envelope of a-c. voltage
(b) Angular displacement
(c) Field current
(d) Exciter voltage

A regulator has been developed by Mr. C. A. Nickle which practically accomplishes this and, therefore, makes it possible to obtain large gains in maximum power above the steady-state limit: Its characteristics are referred to later, and are discussed in detail by Nickle and Carothers in a companion paper. Oscillograms of the line voltage, field current, and excitation voltage under dynamic stability are shown in Figs. 2A and 2B. (The record of field-current oscillations was magnified by inserting a constant d-c. component in the oscillograph circuit in opposition to that due to the field current.) In 2A a relatively large, damped oscillation is shown under the condition of operation at

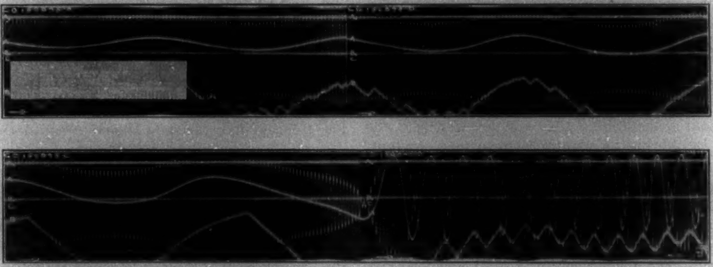
405 kw., the steady-state power limit being 110 kw. The test set-up is shown in Fig. 3. Fig. 2B shows a cumulative oscillation and breakout. In this case the power was only 370 kw., but the regulator was not adjusted at the optimum setting. The negative resistance was too large, thus introducing negative damping and consequent cumulative oscillation. But in both cases it will be noted that the variation of the average (that is, taking the average of the ripples) exciter voltage is substantially in phase with the field current variation; and hence a large component is exactly in phase, thus providing the effect of negative resistance.

But even if the terminal voltage variations are irregular, the regulator will cause the variation of the average exciter voltage to conform substantially to the same pattern, only reversed. That is, the exciter voltage will be up when the a-c. voltage is down, and vice versa. And since the field current variation is also of a similar, but reversed, form with respect to the a-c. voltage variation, it means that the exciter voltage will substantially follow the field current, even for irregular variations. Thus, in general, the effect of negative resistance is afforded by the regulator.

However, negative resistance is not an unmitigated advantage. It affords increased synchronizing power, but does so at the expense of positive damping. Damping due to the field winding is a very important factor in dynamic stability. As the effect of ohmic resistance is gradually eliminated by the foregoing means, the synchronizing torque is correspondingly increased,[17] but the net damping is decreased; and when the exciter voltage more than compensates the $i\,r$ drop, negative damping results. That is, under this condition any oscillation will cumulate and, unless other damping devices are present, will cause breakout. This is



(A) 405 Kw. Maximum Power Obtained with Adjustment of Regulator to Give Optimum Value of Equivalent Negative Resistance



(B) Cumulative Oscillation and Break-out at 370 Kw. Obtained with Regulator Adjustment to Give too Large Negative Resistance

Fig. 2—Oscillograms of Maximum Power with a Type A Regulator. Set-up Shown in Fig. 3. Steady State Power Limit, 110 Kw.

Curve B—Exciter armature voltage 1 mm. = 3.09 volts as measured from zero line $A_O$
Curve C—A. C. line voltage 1 mm. = 4.87 volts. P. T. Ratio = 20:1.

illustrated in Fig. 2B. The value of the negative resistance is fixed by regulator adjustment, as explained by Nickle and Carothers.

An amortisseur winding should thus be of some advantage when the machine is operating near the point of maximum power.

The phase relations of the various components of excitation voltage should be further considered. The period of oscillation is of the order of 1 sec.—*i. e.*, of a frequency of one cycle per second. Since $\frac{L}{R}$ of the field for this condition is of the order of 2 to 3 sec., $\frac{X}{R}$ at one cycle per second would be of the order of 12 to 18. It follows that the alternating component of field current due to the pulsating exciter voltage will lag by approximately 90 deg. Hence, referring to Fig. 1, we may say for the purpose of rough illustration that that component of alternating exciter voltage which is in phase with the given alternating component of field current (in phase with the angular position), produces a component of field current and, therefore, a torque, in time quadrature. This torque is thus in phase with the motion and is, therefore, negative damping, tending to increase the motion. It opposes the positive damping represented by the alternating component of $i\,r$ drop, and when it is in excess of the latter, cumulative oscillations follow.

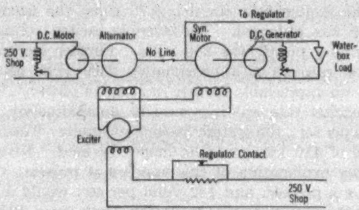

FIG. 3—TEST SET-UP WITHOUT TRANSMISSION LINE

Machine Ratings
Alternator and motor TS-6-435-1200-4000/2300 volts
D-c. motor and generator MPC-6-300-1200-250/275 volts
Exciter MP-4-17-700-250 volt 68 amperes
Synchronous reactance (without saturation) of generator = 46 ohms
$W\,R^2$ of rotor (total) = 2880 lb-ft.$^2$

The other component of exciter voltage which is in time quadrature with the field current, produces a component of field current in phase opposition to the given field current. It thus decreases the synchronizing torque.

The foregoing relations are of course not strictly true, but they will serve to illustrate the general nature of the effect of impressing different components of excitation voltage, and to show how regulators with different operating characteristics may produce very different results of maximum power and stability.

The point of view of evaluating the effect of the exciter and regulator in terms of equivalent circuit constants in the field can be developed further. As already explained, that component of exciter voltage which is in phase with the field current gives the effect of negative resistance. Now the component which is in time quadrature (lagging), gives the effect of an inductance in the circuit—*i. e.*, equivalent to increasing the transient reactance. This component is undesirable, at least so far as the maximum power is concerned. It follows that a component in phase opposition to the latter would give the effect of negative reactance, and would thus be advantageous.

With the new regulator, which impresses an exciter voltage in phase opposition with the line voltage variation, and therefore in phase with the field current variation, operation under dynamic stability was carried far beyond the steady state or static power limit—in one particular test among many, under the set-up of Fig. 3, to over 4 times the static limit, *i. e.*, to 450 kw.

Digressing for a moment in retrospect, the author's view regarding one aspect of this problem has changed. In the earlier stages of this general investigation[7–14] when a study was being made to find means for compensating the effects of armature reaction on the field, it appeared that any scheme involving a vibrating regulator actuated by the a-c. voltage, and controlling an exciter, would be too sluggish, and that therefore some other scheme, such as the mercury arc and series exciter, would be necessary. Subsequent investigations, however, have shown that on account of the inherent character of the relationships between the line voltage, angle, and field current, as shown in Figs. 1 and 2, the excitation voltage rate does not have to be extremely high in order to effect such a compensation. Taking advantage of the time element afforded by inertia and damping, the average exciter voltage can be made to vary, up and down, in time phase opposition with the line voltage variation, and, therefore, approximately in time phase with the field current—provided the regulator gives prompt and appropriate response in excitation voltage. In other words, more can be accomplished by a vibrating regulator than had been anticipated in the early stages of the investigation.

The foregoing discussion has centered largely about the regulator and the alternator characteristics. It may be asked, what effect has the exciter voltage build-up rate upon the maximum power which can be transmitted under dynamic stability?[16] Such operation obviously depends in a decisive way both upon the characteristics of automatic voltage regulators, and the quickness of response of the excitation source. An excitation *system* is a composite, and not a number of independent elements. An exciter can obviously do no more than react, in accordance with its inherent characteristics, to the conditions which are imposed upon it by the regulator and the connected circuits;

while the regulator can only control the particular exciter, whatever it may be, according to the regulator's inherent characteristics, and as it is influenced by the controlling and controlled circuits. An excitation system is thus like most other systems—if all components are not properly constituted and coordinated, it will not function efficiently.

It happens, however, that the exciter voltage rates obtainable from standard exciters are high enough to sustain dynamic stability, as shown under the heading, TESTS. The range of rates of voltage build-up of standard exciters has been given under EXCITATION CONTROL DURING SYSTEM DISTURBANCES. This does not mean that quick-response excitation should not be used if its use is desirable for some other reason—say to apply excitation quickly on the occasion of a system disturbance. If the regulator has the right characteristics, it can apply quick-response excitation as readily as it can apply the excitation from standard exciters, and obtain the same maximum power, as shown later.

A very definite distinction, however, must be drawn between the rate of variation, up and down, of exciter voltage as the contacts close and open, on the one hand, and the consequent rate at which the average excitation voltage changes, on the other. This difference may be very great depending upon the type of regulator.

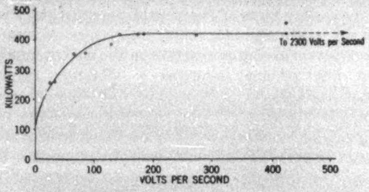

FIG. 4—MAXIMUM POWER AS A FUNCTION OF THE EXCITER VOLTAGE BUILD-UP RATE, FOR THE TEST SET-UP OF FIG. 3, USING TYPE A REGULATOR

The question regarding the relative influence of regulators and of the voltage rate of exciters on the maximum power which can be transmitted under dynamic stability will now be answered by tests.

## TESTS

One particular test set-up, among a large number, is shown in Fig. 3, including the ratings of the machines. The tests were run at about half voltage in order not to overload the d-c. generators under the condition of the large increase in power. Even at half voltage on the synchronous machines, the d-c. output (normal voltage) at maximum power was more than normal. The alternator fields were wound for 250-volt excitation. The exciter was a 250-volt machine, operating at 50 volts at zero power, 200 volts at the ultimate maximum power—*i. e.*, at 415 kw., (Fig. 4).

There are four principal voltage regulators with which comprehensive maximum power tests were made, including tests at different exciter voltage rates. Others were tested, but not so comprehensively. The four types are:

A. Original model of the regulator embodying the new principle. This will be referred to as type *A* in the following discussion.

B. New commercial form embodying, in the main, the characteristic features of the original model. This will be referred to as type *B*.

C. Older commercial form with d-c. coil, which will be designated as type *C*.

D. The usual commercial form without d-c. coil, which will be designated as type *D*.

In tests with type *A* regulator and with an exciter voltage build-up rate of 24 volts per sec. (as measured by oscillograph at the exciter terminals under the actual condition of maximum power), a value of power equal to twice the fixed-field, or steady-state value, was obtained; and with a measured build-up rate of 142 volts per sec., (obtained by changing connections in the exciter field circuit), 3.75 times the fixed-field value was obtained. The average exciter voltage at maximum power was 200 volts. Further increase in exciter rate up to approximately 2300 volts per sec. gave no appreciable further increase in power. When the exciter rate was increased to approximately 3000 volts per sec., the system became unstable. The maximum of 415 kw. could no longer be held. No satisfactory explanation of this appears at present. Now 24 volts per sec. and 142 volts per sec. would not be termed quick-response excitation, even on a 125-volt exciter; but here it was a 250-volt exciter. Thus, those rates would correspond to 12 volts per sec. and 71 volts per sec. on a 125-volt exciter. It was the most sluggish exciter which had been found.

The only interpretation which the author has been able to make of those facts is that the regulator played a decisive part in obtaining the improvement in power limits, and that quick-response excitation had nothing to do with it, because quick-response excitation was not used in obtaining the results; and moreover because, when the rate of exciter build-up was increased to a high rate, no further improvement was found. Fig. 4 shows the curve relating the measured exciter voltage rate and maximum power, as obtained in the test set-up of Fig. 3.* The build-down rate was of the same order as the build-up rate. A different series of tests on the same apparatus, but showing about 5 per cent greater maximum power is shown by Nickle and Carothers. A more detailed reference will be made later to the exciter build-up rate and its relation to maximum power.

Another test under the conditions of Fig. 3 was taken, using type *B* regulator. The maximum power obtained was 385 kw., *i. e.*, 3.5 times the steady-state limit; and hunting did not begin until a load of 250 kw. was passed.

---

*This may answer satisfactorily the question raised in the literature, reference 16.

The test set-up shown in Fig. 5 includes an artificial 500-mile transmission line between the motor and generator, the reactance of the line being approximately 1.5 times the synchronous reactance (46 ohms) of the generator, the generator and motor being duplicate machines. The machines were each regulated at 2240 volts. In this case, the static power limit was 44 kw., the infinite bus value being 61 kw. With the type *A* regulator, 55 kw. was transmitted, *i. e.*, received at the motor. This is 90 per cent of the infinite-bus value. This result was obtained with two different exciter rates, namely, 500 and 250 volts per second. The average exciter voltage at the maximum power was 66 volts.

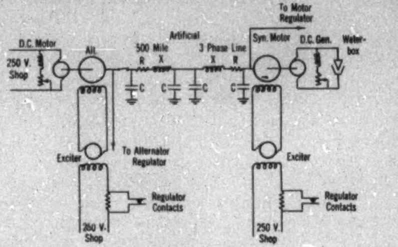

FIG. 5—TEST SET-UP WITH ARTIFICIAL 500 MILE TRANSMISSION LINE

Machine ratings
Alternator and motor TS-6-435-1200-4000/2300 volts
D. C. motor and generator MPC-6-300-1200-250/275 volts
Exciters MP-4-17-700-250 volts
$X = 35.5$ ohms
$R = 5.0$ ohms
$C = 3.75$ mf.

The increase in maximum power was naturally less here than in the case of Fig. 3, because the line impedance drop is, in a sense, an unregulated factor in the situation; that is, since the voltage is regulated at the machine terminals, the machine impedance drops only are corrected. For instance, if the voltage at the middle of the line, instead of at the ends, were regulated at normal value, the increase in power would be much greater. The voltage at the machine terminals would then be greater, since in that case the line reactance would in a sense be equivalent to an addition to the synchronous reactance under the condition of Fig. 3.

Referring again to the tests, a number of regulators has been tried in various factory tests using the same machines and circuits. None of the former commercial models in these comparative tests could approach the maximum power obtainable under dynamic stability with the new model. In certain early factory tests with 5-kv-a. machines, the new regulator alone (type *A*, and type *B*) made possible a decisive increase in maximum power above the steady-state limit. The maximum power obtained with these types was 11.0 kw., the steady-state limit being approximately 7.0 kw.,† and the infinite-bus value, calculated, was 12 kw. With the other regulators, including types *C* and *D*, and also a commutator type, the synchronous machines broke apart at substantially the steady-state limit of power.

In later tests, however, in which larger machines, with relatively larger inertia and damping, were used, it was possible with commercial regulators to obtain an increase above the steady-state limit. In the tests of Fig. 3 (no impedance between machines), in which the new regulator type *A* gave 3.75 times that limit, with practically no hunting until 3.5 was passed, type *D* without d-c. coil gave only 1.75 to 2.0 times that limit with serious hunting. In the latter case, hunting began as soon as the steady-state limit was passed, in spite of the most favorable adjustment, and became progressively worse with increase in load, hunting out of step at the above values of power. With the new commercial regulator type *B*, however, hunting began at about 2.5, and at this value the stability was comparable with that of the commercial type *D* just after passing the steady-state limit, *i. e.*, at 1.0. In the case of the older commercial type with d-c. coil, (type *C*), only a small increase was obtained. The machines hunted out of step soon after steady state was passed. Fig. 6 shows the results for all four cases, giving the maximum power which could be held in synchronism. Fig. 7 gives the same results with an indication of the extent and character of hunting.

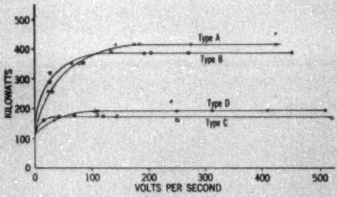

FIG. 6—MAXIMUM POWER AS A FUNCTION OF THE EXCITER VOLTAGE BUILD-UP RATE FOR THE TEST SET-UP OF FIG. 3, USING THE DIFFERENT TYPES OF REGULATORS

Dynamic stability can be sustained also by hand juggling of the exciter rheostats. With rheostats and field-circuit connections such that the exciter rate would be 500 volts per sec. if all resistance were suddenly cut-out, it was possible to sustain over twice the steady-state value of power by hand control of the rheostats. Watching the line voltmeter, the field rheostat was shifted back and forth to correct for the changing voltage. When the voltage started to decrease, the rheostat was set by guess at a point to correct the decrease; and as it began to increase, a similar correction was made. It is to be noted that the rheostat was not all cut-out, and all cut-in, as with a regulator; instead, the change in resistance was relatively small. Hence the actual rate of exciter voltage was correspondingly small. Even so, it was possible to obtain an increase of 100 per cent above the steady-state limit by hand juggling.

---

†These results are given by Messrs. Nickle and Carothers. The test set-up involved two duplicate synchronous machines connected through a line reactance equal to two-thirds of the synchronous reactance of either machine.

### REGULATOR CHARACTERISTICS

The above results are very interesting in view of the parallel drawn by Messrs. Nickle and Carothers, between such hand control and the inherent action of a regulator—such as the commercial type $D$ referred to—which operates on the principle that a definite ratio (time closed) ÷ (time open) exists for each value of a-c. voltage. Thus, these authors show that for small changes in the average exciter voltage, the effective exciter voltage rate from the one voltage to the other is not the rate corresponding to the closed contact, as might at first be supposed, but a much smaller rate—corresponding, much as in hand control, to the relatively small shift from one resistance to another. A small drop in a-c. voltage merely changes the ratio (time closed) to (time open) on the regulator corresponding to the new average resistance necessary for regulation; and the average exciter voltage changes according to a correspondingly slow transient, and not according to the total exciter rate. For illustration, if the above ratio does not change at all, the exciter voltage varies up and down at full exciter rate, but the average value does not change; and if the ratio does change, following a small change in a-c. voltage, it merely sets a new average resistance, *i. e.*, a setting for a new average exciter voltage. But the latter reaches the new value by a relatively slow transient corresponding not to the rate with contacts closed, but merely to the change in average resistance. This is true, in that range of a-c. voltage variation in which the regulator functions normally—*i. e.*, in which the contacts vibrate. This is of the order of ± 10 per cent. If, for instance, the voltage falls below the lower critical value, the contacts close and stay closed; in which case the total exciter rate is the effective rate. But this condition does not exist in operation under dynamic stability. It is thus somewhat analogous to hand juggling, and it is therefore not surprising that the maximum power obtained in test in the two cases was about the same.

The type $A$ regulator, however, operates on an entirely different principle—a principle which no other regulator has embodied; and this explains why the increase in maximum power is much greater when it controls the voltage. The principle is: *for a given change in a-c. voltage, the new average exciter voltage for the new condition is reached at a continuous voltage rate equal to the actual total rate of the exciter. This is initiated promptly, and is true for all a-c. voltage changes, small as well as large.** Other regulators may initiate their response promptly, and, moreover, the effective excitation voltage rate may be equal to the rate of the total exciter voltage for *large* changes in a-c. voltage. But no other regulator, to the author's knowledge, affords this equality of voltage rates for relatively small changes in a-c. voltage—such, for instance, as would be encountered normally under the condition we have been considering, namely, dynamic stability. Operating according to the above principle, the new regulator thus causes the average exciter voltage to keep pace with the alternator field current, as in Fig. 1, and therefore provides the effect of negative resistance. (The value of negative resistance is proportional to the resistance in the d-c. coil of the regulator, as explained by Nickle and Carothers. It can thus be easily adjusted for the optimum condition.)

The circumstance that makes it possible for the exciter voltage to follow the field current so closely is that the variations of the latter are relatively slow (of the order of one cycle per second—and this is roughly true for power systems in general) and are also relatively small. For numerical illustration, if the amplitude of variation were, say 10 per cent, of the average field current (which would be a relatively high variation), this would mean that, for complete resistance compensation, the average exciter voltage must vary 10 per cent, and in phase. And the required rate of exciter voltage change would be,

$$\frac{d\,e}{d\,t} = \omega\, e_0 \cos\,(\omega\, t + \alpha)$$

where the voltage $e_0$ is the amplitude of the variation, and $\omega$ the corresponding angular velocity. If the amplitude $e_0$ is 10 per cent—*i e.*, total variation of ± 10 per cent—and the frequency is one cycle per second, the maximum rate (during the cycle) of the average excitation voltage is,

$\omega\, e_0 = 2\,\pi \times 10$ per cent $= 62.8$ per cent of the steady component per second.

Hence, assuming that the exciter is operating at 80 per cent of the rated voltage of say 250 volts, the maximum voltage rate would be roughly

$$0.62 \times 0.8 \times 250 = 124 \text{ volts/sec.}$$

This, of course, would be the lowest permissible value of the maximum rate under the assumptions. It will be noted that this is of the order of the lowest voltage rate at which maximum power was attained—Fig. 4.

Thus, summing up the new regulator characteristics, it operates on a unique principle which makes it possible, on account of the relatively slow oscillation in dynamic stability, to impress an excitation voltage substantially in phase with the field current variations, therefore affording the effect of negative resistance, as illustrated in Fig. 2. It will be observed that the phase displacement between the field current and excitation voltage corresponds to only 2 cycles of a-c. voltage, *i. e.*, about 12 deg., since the cycle of variation corresponds to one second. In other words, the in-phase component is approximately 98 per cent of the total; the quadrature component, only 20 per cent.

---

*For the detailed treatment of this, see companion paper by Nickle and Carothers, p.957.

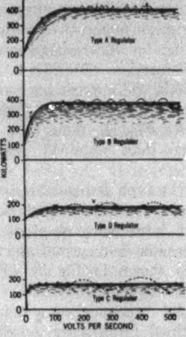

FIG. 7—THE SOLID CURVES ARE THE SAME AS THOSE SHOWN IN FIG. 6

The shading is intended to indicate the intensity and range of hunting. Thus heavy shading indicates serious hunting, and no shading indicates practically stable operation. The dotted line, with time as abscissa, indicates the general character of the oscillation corresponding to imminent break-out

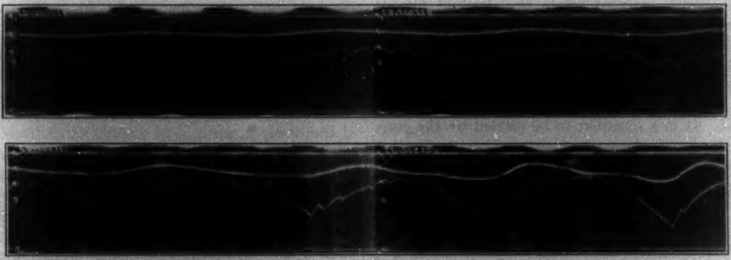

FIG. 8—OSCILLOGRAM OF MAXIMUM POWER TEST WITH A TYPE D REGULATOR ADJUSTED FOR OPTIMUM CONDITIONS. SET-UP SHOWN IN FIG. 3. STEADY STATE POWER LIMIT, 110 KW. 190 KW. MAXIMUM POWER OBTAINED

Curve A—Exciter armature voltage 1 mm. = 3.43 volts (as measured from zero line $A_O$)
Curve B—A-c. line voltage 1 mm. = 5 volts. P T. Ratio = 20:1
Curve C—*T S* field current 1 mm. = 0.135 amperes (true zero line displaced 0.09 mm. above reference line $C_O$)

Now consider the type *D* regulator in these terms. From the principle of its operation, already discussed, it is clear that for a given change in a-c. voltage, a new setting of average resistance, corresponding to the new, anticipated average excitation voltage, is instantly effected, and a transient of the average excitation voltage is started, the rate of the transient depending upon the magnitude of the change. For a small change the rate is very low; for a large change, it approaches the full exciter voltage rate. Hence in an oscillation, and especially a small oscillation, in that range of the voltage variation in which the voltage is changing only slightly, as immediately after the maximum or the minimum, practically no change in the average excitation voltage occurs. And as the variation reaches the larger slopes, the excitation voltage begins to change more rapidly. This means inherently a lag in phase. Thus, unlike the type *A* regulator, here the effect of the regulator and exciter, instead of being a negative resistance, is equivalent to shunting the resistance of the alternator field circuit by an inductance. For any spontaneous change in the field current, the *i r* drop, due to the added current, is present in the first moment, but gradually disappears as the current is taken by the shunt inductance which has no resistance; and the rate at which the *i r* drop disappears depends upon the magnitude of the change in the alternator field current. This therefore represents the conditions as outlined for the type *D* regulator. Thus, the exciter voltage is represented by the voltage across the parallel circuit of the inductance and resistance. As such, it must be out of phase with the total current. Fig. 8 shows the actual phase relations under a test in which the conditions were the same as those in Fig. 2, except the type *D* regulator was used instead of the type *A*. It will be noted that the phase displacement between the average excitation voltage and the alternator field current corresponds to about 10 cycles—*i. e.*, about 60 deg. lag. Thus, only 50 per cent is in phase, 86 per cent in quadrature (lagging). This explains why only 190 kw. could be obtained instead of 405 kw. in Fig. 2. Fig. 8 shows the conditions at the maximum power, just preceding break-out. The regulator was adjusted at its optimum setting.

In the case of type *C*, since it also is not so responsive to small voltage changes, it naturally must also permit large angular and voltage oscillations, just as soon as the dynamic state of operation is entered; and thus the increase in maximum power should also be less than that of the types *A* and *B*, and the hunting more severe. And this is what actually happens, as indicated in Fig. 7. While this regulator serves well the general purpose for which it was designed and for which it has been and is being widely used, it is nevertheless seriously handicapped—even somewhat more than the type *D*—in connection with operation under dynamic stability. For this state of operation, a new regulator with a new principle of operation is required, such as types *A* and *B*.

### SUMMARY AND INTERPRETATION OF CONCLUSIONS

What interpretation is to be placed on the foregoing discussion and facts? Should quick-response excitation systems be always used, and how "quick" should the response be? What element in the excitation system has made possible the large gains in maximum power reported in the paper? What is the significance of the gains regarding the future of power transmission?

Two predominating facts in the field of power transmission have changed the aspect of this subject, and have introduced two corresponding problems in excitation systems. The growing demand for increased reliability of service has required quicker response of excitation systems on the occasion of system disturbance, in order to reduce the voltage drop to a minimum. And the increase in the load per transmission circuit, and in the specific loading of synchronous machines, has brought rather sharply to the fore the limit of maximum power, which formerly was encountered only infrequently.

Quick-response excitation is of distinct advantage in important power systems where the demand for increased reliability of service is pressing; and this, of course, includes many of them. The character of the excitation system—whether of moderately rapid voltage rate, or an extremely rapid rate together with a high "ceiling" voltage—is, to a large degree, a matter of economics. It is a question to be settled by the conditions of the particular case.

But the question involves the very important aspect of increased short circuit current. The use of quick response excitation means, in general, larger switches. The general trend in this direction should be duly considered in the choice of an excitation system.

Radical increase in maximum power above the steady-state limit—*i. e.*, above the value of maximum power which has heretofore been the practical limit—has been obtained in test. This involves a state of operation which is fundamentally different in character from that of the usual present day power system. This state of operation is termed *dynamic* stability, as distinguished from the condition of steady state, or *static* stability.

The increase in maximum power has been made possible by a new and unique voltage regulator. The principle which distinguishes this regulator, designated in the paper by "type *A*", from all other existing types is this: *for a given change in a-c. voltage, the new average exciter voltage for the new condition is reached at a continuous voltage rate equal to the actual total rate of the exciter. This is initiated promptly, and is true for all a-c. voltage changes, small as well as large.* The effect of the type *A*, or of type *B* which operates on the same principle, is to provide an equivalent negative resistance, thus giving a maximum power corresponding to constant flux linkages in the alternating field circuit. In other words, it gives a component of variable excitation voltage which is at all moments equal to the $i\,r$ drop, thus compensating for the resistance—and therefore for the armature reaction. See Fig. 2. This made it possible to obtain in test a maximum power of 415 kw. on a system, Fig. 3, for which the steady-state limit was 110 kw. See Fig. 4. This is a much greater maximum power than obtained with any other regulator.

The effect of the type *D* regulator is equivalent to shunting the resistance of the field circuit with an inductance, thus introducing a phase displacement between the alternator field current and the excitation voltage. This is shown in Fig. 8. The maximum power is therefore less, being 190 kw., as compared with 415 kw., since the resistance cannot be completely compensated without introducing the effect of inductance. See Fig. 7.

For relatively large changes in a-c. voltage—say of the order of 10 per cent above, or 10 per cent below—the rate of the effective d-c. voltage approaches the total exciter rate with contacts closed; and for still larger changes in a-c. voltage, as in the case of a short circuit, the contacts close and stay closed, thus giving the full exciter rate. This type is thus appropriate for a normal regulator below the steady-state limit, or in the case of short circuits; but it is not so suitable for quickly regulating for small voltage changes, as required under dynamic stability.

The type *C* regulator also delays action, on account of the dashpot, until large angular oscillations are set up; and its consequent effect is equivalent to inserting an inductance shunt around the resistance, as in the case of type *D*. Hence the maximum power is also lower and the hunting is more severe than in the case of types *A* and *B*.

All other commercial types, such as the "face plate regulator" and its derivatives, and the commutator type, are still more sluggish for small voltage changes. Some of these types are efficacious for quickly changing excitation on the occasion of short circuits, but they are not appropriate for sustained operation under dynamic stability. Thus, the difference between the large increases in maximum power which have been obtained by using the new regulator, type *A*, as reported in the paper, and the increases obtained by other regulators and by hand control, is explained by the fact that the new regulator functions according to an entirely different and novel characteristic, which was chosen with respect to the particular requirements of this problem.

Quick-response exciters are not essential to operation under dynamic stability. An increase of 100 per cent in power above the steady-state limit was obtained with the type *A* regulator controlling an exciter voltage rate of 24 volts sec. on a 250 volt exciter; and an increase of 275 per cent, with a rate of 142 volts/sec. No further increase was obtained when the exciter voltage rate was further increased, even to 2300 volts/sec. Thus quick-response excitation gave no more maximum power than the low rates of ordinary exciters. But it gave as much —*i. e.*, it did not impair the results, until the high rate of 3000 volts/sec. was reached. (Where an extremely high exciter voltage rate is used in connection with short circuits, this rate is applied only on the occasion of a short circuit. Normally it is not in the circuit.) Then instability occurred. It is thus concluded that quick-response excitation was not essential to the maximum gain in power limit obtained in the tests, because the gain was made without the use of such excitation.

But this does not mean that such an excitation system may not be desirable in a system normally operated under dynamic stability. It surely would be desirable, but for another reason—namely, to reduce the voltage drop during system disturbances, which is also the reason it is used on present systems normally operating below the steady-state limit.

It should be added that the type *A* and type *B* regulators possess the required characteristics for controlling excitation both under dynamic stability and under the condition of system disturbances such as short circuits. That is, they possess characteristics suitable for general application.

The most important aspect of the results is the possible influence on the future of power transmission. There are two phases of this which should be considered. One relates to the possible increase in the output of the synchronous machines for large central stations, or in special cases of industrial plants where momentary demands of power are greater than could be carried under steady state operation, the other, to long distance transmission.

With respect to increasing the output of synchronous machines, the foremost limitations in design formerly were heating and voltage regulation. The latter was practically removed by the advent of the automatic voltage regulator, and the former has been progressively raised, principally by improvements in ventilation, and by the reduction of energy losses—*i. e.*, sources of heat. Consequently, the rated output has gradually approached, and has finally reached the immediate range of maximum power. Thus a new limitation is encountered. Although one cannot draw general conclusions from factory tests, yet from both the test results and theoretical considerations, there appears to be no reason at this time why the limitation of maximum power could not be set much higher by the proper use of the new regulator, thus making possible a continued progress in higher specific loading of synchronous machines. The prospects are still more hopeful for satisfactory application in those special cases where considerable momentary overload is required from time to time. And even if normal operation were to be below the steady-state limit, less safety margin would be required, since the system would be capable of operating above the steady-state limit. That is, a new margin may thus be created by the regulator.

As to long distance transmission, the results appear very promising. With the new regulator, a maximum power equal to 90 per cent of the infinite bus value was obtained over an artificial 500 mile straightaway line. The economic limitations in the power projects involving long transmission distances have been widely discussed in the literature. The situation has been faced that the maximum power which could be transmitted over very long distances was not sufficient to justify the necessary investment. The results of the present investigation are promising with respect to the possibility of removing some of those limitations and thus placing such projects on a much more attractive basis. Future developments will show whether such hopes are justified.

There is another factor which appears to be favorable in considering the application of the regulator on large machines. In such machines the mechanical inertia is relatively greater, and the electrical transients inherently longer than in the small machines used in this investigation. Thus, it would appear that the regulator would operate under still more favorable conditions when controlling the larger machines.

# Automatic Voltage Regulators

## Application to Power Transmission Systems

BY C. A. NICKLE[1] and R. M. CAROTHERS[1]
Associate, A. I. E. E. Member, A. I. E. E.

WITHIN a relatively short time conditions in transmission systems, as regards continuity of service, and maximum power, have radically changed. A few years ago, the amount of power transmitted over important lines was relatively small compared with their ultimate transmitting capacity. In such cases, the systems were inherently stable, and there was a reasonable margin of power with respect to load swings and short circuits. Automatic voltage regulators were used at that time chiefly for maintaining more uniform voltage conditions than could be obtained by intermittent adjustment by hand control. Different types of regulators for this purpose have given satisfactory service for a number of years. However, conditions have gradually changed. Within the last few years the power to be transmitted has increased to such an extent that it has now become necessary to consider means seriously for increasing the maximum power and for insuring continuity of service during transient disturbances, such as load swings and short circuits. The object of this paper is to present the results of an extended investigation along these lines. A new regulator is described which will accomplish the above purposes, and the theoretical analysis is confirmed by test results.

### FACTORS INFLUENCING POWER LIMITS

In order to facilitate an understanding of the principles involved and the functions of voltage regulators and exciters in a transmission system, some of the factors which determine the power limit of a system will be considered briefly. When the shaft load of a synchronous motor connected to an alternator, directly or through a transmission line, is gradually increased, a point is soon reached where no more electrical power can be supplied to the motor. The amount of power which can be thus supplied depends upon the total reactance between the generator and motor, including their internal reactances, and upon the values of excitation which exist. Small values of excitation give small values of breakdown power, and large values give large values of breakdown power.

The magnitudes of the excitation which can be applied to the machines are limited by the condition that certain predetermined terminal voltages shall not be exceeded. For different sets of fixed excitation values there will be corresponding values of terminal voltages and power when breakdown occurs. Under these conditions of fixed field excitation, the maximum power obtained is termed the steady state or static power limit for those terminal voltages. For instance, if the power on a given system is 100,000 kw. when the machines pull apart, and if the terminal voltage is 220,000 volts at this instant, all excitations being held constant, then 100,000 kw. is the steady-state power limit for operation at 220,000 volts.

Under proper conditions of variable excitation it is possible, however, to operate beyond this limit. The first experimental evidence that this was practicable was obtained[2] by the use of devices which increased the excitation as a function of load current, and thus compensated for armature reaction simultaneously with its occurrence. While recognizing the advantage of such factors as mechanical inertia, damping, and electromagnetic transients in stabilizing operation during system disturbances, earlier investigation, including tests with existing standard commercial regulators, had nevertheless not brought out the full possibility of utilizing these factors in producing stable operation above the steady-state limit. Indeed they definitely showed that even if it were possible to hold the machines in synchronism significantly above that limit, this was accompanied by prohibitive hunting. Later investigation, however, showed that stable operation beyond the steady-state limit was possible with control by a vibrating contact regulator having special and unique characteristics. This will be fully discussed later.

### DYNAMIC STABILITY

When operating below the steady-state power limit, machines are inherently stable, *i. e.*, with no changes in the electrical constants, certain increments of shaft power may be applied without loss of synchronism, and the machines are thus considered to be in static equilibrium. For values of transmitted power above the static power limit, conditions are radically different.

Although equilibrium may exist for certain values of excitation, power, angular displacement, etc., nevertheless, if the excitations remain constant, any increase in shaft load increases the angular displacement with a resultant decrease in transmitted power. Thus, for this condition, the rate of change of power with respect to angular displacement is negative, and any change in shaft load produces cumulative action. Fortunately, due to inertia of the moving parts, the damping action of short-circuited rotor windings, and the tendency of the flux linking the field winding to remain constant,

the process of falling out of step is relatively slow; and if the excitations are properly adjusted following a change in shaft power, the machines can be held in equilibrium.

Similarly, when a decrease in shaft power occurs, the angular displacement decreases with a resultant increase in transmitted power. For conditions of fixed excitation, the machines will thus continue to approach each other in phase position, and will come to equilibrium at a smaller angle for which the machines are inherently stable.

Dynamic stability may be further illustrated by considering the equations of the simple case of two identical cylindrical rotor machines, connected directly together electrically.

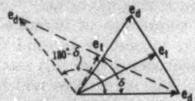

Fig. 1—Vector Diagram for Two Identical Cylindrical Rotor Machines on the Same Bus

The power as a function of the excitations or nominal voltages (assumed to be the same on both machines) and the angular displacement between the rotors, is[3]

$$P = \frac{e_d^2}{x} \sin \delta \qquad (1)$$

where

$e_d$ = nominal voltage corresponding to the excitations on the generator and motor.

$x$ = total reactance of both machines.

$\delta$ = the angular displacement between the rotors.

From this relation, it may be seen that the same power may be transmitted at two values of $\delta$, *i. e.*, one angle $\delta'$ less than 90 deg., and another angle (180 deg. $- \delta'$) greater than 90 deg., for given values of excitation and reactance. The vector diagram is as shown in Fig. 1. From this figure, it is evident that the terminal voltage is different for these two operating angles and is given by the equation

$$e_t = e_d \cos \frac{\delta}{2} \qquad (2)$$

From the standpoint of power transmitted, it is thus immaterial whether operation occurs at $\delta'$, less than 90 deg., or at 180 deg. $- \delta'$, greater than 90 deg., for given values of nominal voltage. However, the terminal voltage will be less in the latter case, the comparison being cos (90 deg. $- \delta'/2$) or sin $\delta'/2$, with cos $\delta'/2$. Therefore if the terminal voltage is to be the same, we must operate at greater excitations at 180 deg. $- \delta'$ than at $\delta'$ and consequently more power can be delivered.

It is considerably more difficult to maintain equilibrium at 180 deg. $- \delta'$ than at $\delta'$ since the rate of change of power with angular displacement is negative and the machines are in a state of dynamic balance. Any increase in shaft power will cause breakdown if the excitations are not changed, and any decrease in shaft power will cause the angular displacement to revert to the inherently stable angular displacement, $\delta'$, with a resultant abnormal rise of terminal voltage.

Operation above the static power limit thus necessitates a continually varying excitation. What appears at the present time to be the most suitable means for properly controlling these excitations is an automatic voltage regulator of suitable design.

### Automatic Voltage Regulators

Automatic voltage regulators are of two general types, *i. e.*, the rheostatic type and the vibrating contact regulator. The characteristics of different regulators of the same general type may be essentially different, depending upon the constructional features and methods of control.

Before the introduction of automatic voltage regulators, voltage was controlled by hand adjustment of rheostats in the field circuits of the exciter or alternator. Such control is necessarily rather intermittent and it is evident that a regulator designed to perform the same functions as hand control, but more continuously, would materially improve voltage conditions. The rheostatic type functions in this way, and for certain conditions of operation gives quite satisfactory service.

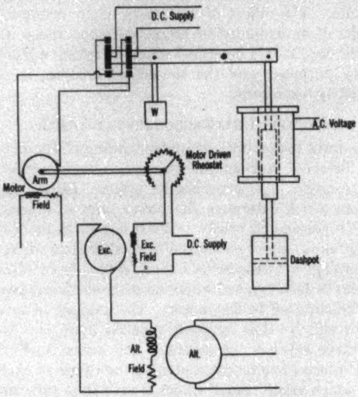

Fig. 2—Schematic Diagram of an Excitation System Controlled by a Rheostatic Type Regulator

This type of automatic regulator in its simplest form consists of a motor driven rheostat, the motor being controlled by relays operated from the voltage which is to be regulated. Fig. 2 gives a schematic diagram of a regulator of this type. When the voltage rises above a predetermined value, the relay connected to the regulated voltage impresses a voltage on the armature circuit of the motor, and the resistance of the motor driven rheostat is gradually increased until the regulated voltage is again normal. Similarly, when the controlled voltage decreases, the relays reverse the voltage impressed on the motor armature, thus causing the resistance of the motor driven rheostat to decrease until the regulated voltage has increased to normal value. When the regulated voltage is normal, the contacts are all open and the motor driven rheostat becomes stationary in that position which will just hold normal voltage for the particular load conditions which exist.

---

[3] Doherty and Nickle, *Synchronous Machines*, Trans. A. I. E. E., 1926, Vol. XLV, p. 927.

This regulator in its simplest form is rather sluggish in action, being merely an improvement over intermittent hand control, and is not adapted for taking care of sudden disturbances, such as short circuits, or for controlling voltage when machines are operating above the static power limit. However, this regulator may be modified in a simple manner to take effective care of short circuits occurring when machines are operating below the static power limit.

When a short circuit occurs, there is a sudden abnormal drop in terminal voltage which seriously reduces the synchronizing power of the synchronous apparatus for given values of excitation, angular displacement, etc. At such times it is essential that the excitations be increased as rapidly as possible to prevent the machines breaking from synchronism. It may also be desirable to decrease the excitation rapidly when short circuits are cleared in order that the system shall not be subjected to abnormal rises of terminal voltage. These rapid changes of excitation during short-circuit conditions may be obtained by means of auxiliary relays, one of which short circuits the motor driven rheostat at such times as the resistance is being decreased, *i. e.*, immediately following a drop in terminal voltage; and another relay which inserts a normally short-circuited resistance in the exciter field circuit at such times as the resistance of the motor driven rheostat is being increased, *i. e.*, immediately following a voltage rise.

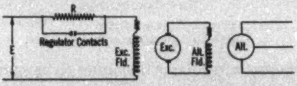

FIG. 3—SCHEMATIC DIAGRAM OF AN EXCITATION SYSTEM CONTROLLED BY VIBRATING CONTACTS

One of the advantages of such a regulator lies in the fact that, by suitable design, the entire regulator may be stationary for relatively long periods of time during steady load conditions, resulting in quietness of operation. The ratio of the time that the rheostat is in motion to the time that it is stationary is largely determined by the voltage sensitivity of the controlling relay. The greater the sensitivity of this relay, the smaller will be the voltage change required to operate the contacts and the motor driven rheostat will be in motion a larger part of the time. With extreme sensitivity, the relays and motor driven rheostat would be in operation all the time and the regulator would be essentially a vibrating contact regulator. The sensitivity of this relay has an important effect upon the possibility of such a regulator controlling operation above the static power limit.

When machines are operating above the static power limit, they are continually in the incipient stage of breakdown. As they begin to break from synchronism, the terminal voltage changes are small, but if these small changes of terminal voltage are not corrected, the machines soon obtain sufficient velocity of separation to make it extremely difficult to restore them to equilibrium at a later instant, regardless of the speed of build-up of the excitation voltage. In order that such a regulator may respond to these small voltage changes, the controlling relay must be made very sensitive to small voltage changes with the result that the regulator will be in operation at all times, even for power transmission below the static power limit. One of the advantages of this regulator is then lost, *i. e.*, still operation over relatively long intervals of time, and it becomes essentially a vibrating contact regulator.

A characteristic common to all vibrating contact voltage regulators is that the amount of excitation is controlled by periodically short circuiting a resistance in the excitation circuit as shown in the simple diagram in Fig. 3.

When the contacts are closed all the time, maximum voltage is obtained at the exciter terminals, and when open all the time, minimum voltage is obtained. By varying the ratio of the time that the contacts are closed to the time that they are open, any value of average exciter voltage between these limits can be obtained.

There are different ways by which a vibrating contact regulator can change the average exciter voltage from one value to another. One method is to close the contacts at once and keep them closed until the desired exciter voltage is reached, vibration then being resumed at the proper ratio of time-closed to time-open to maintain this new exciter voltage.

Another way would be to change suddenly the ratio of time-closed to time-open to a value which will ultimately sustain the new value of exciter voltage. It might seem that, since the ratio of time-closed to time-open is changed suddenly to a new definite value, the new average exciter voltage is immediately obtained. This, however, is not the case, the new average exciter voltage being obtained only after a relatively long transient. The equations for this transient are derived in the Appendix.

Although, in both cases, steps are taken at once to increase the average exciter voltage, nevertheless there is a marked difference in the time required to attain this new value. When the contacts close and remain closed until the new average exciter voltage is reached, the exciter voltage builds up at the inherent magnetic rate of the exciter, and, as a function of time, will appear as in Fig. 4. It is evident that for this case, the maximum voltage rate possible is obtained from a given excitation system.

When the ratio of time-closed to time-open is merely changed from one value to another, *normal vibration of the contacts is not momentarily interrupted*, and the transient appears as shown in Fig. 5.

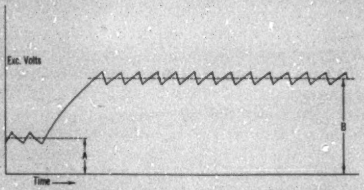

Fig. 4—Variation of Exciter Voltage as a Function of Time for the Case of a Sudden Drop of Alternator Voltage

Contacts close and stay closed until the new value of exciter voltage is reached

The difference in time required for a given change of exciter voltage can be readily appreciated by inspection of Figs. 4 and 5. As seen from Fig. 5, any regulator which operates on the principle of suddenly changing the ratio of the time-closed to the time-open of the contacts, causes the rate of change of average exciter voltage to be very seriously reduced below its inherent or maximum rate, and is seriously handicapped for operation under conditions of dynamic stability. In other words, such a principle used in a scheme of voltage regulation makes the effective voltage rate of the exciter much lower than the possible rate which might be obtained.

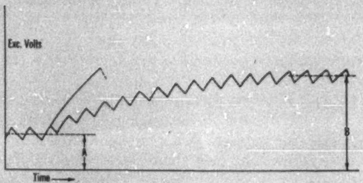

Fig. 5—Variation of Exciter Voltage as a Function of Time for the Case of a Sudden Drop of Alternator Voltage, When the Ratio of Time-Closed to Time-Open of the Contacts Suddenly Changes

Oscillographic verification of the curves shown in Figs. 4 and 5 are shown in Figs. 6 and 7. In making these tests to determine the effect on the exciter voltage of a sudden small reduction in the a-c. voltage, a separate source of voltage, not controlled by the regulator, was impressed on the control coils. The relays of the regulator controlled the terminal voltage of an exciter in the usual way and the oscillograms were taken of the variation in exciter terminal voltage when the amplitude of the impressed voltage was suddenly decreased.

The difference in effective exciter voltage rate for the two cases, particularly for very small changes of impressed voltage, is so marked that a regulator operating on the first principle can effectively control machines in stable operation far above the static power limit, whereas a regulator operating on the principle of suddenly changing the ratio of time-closed to time-open of the relay contacts, gives about the same results as good hand control.

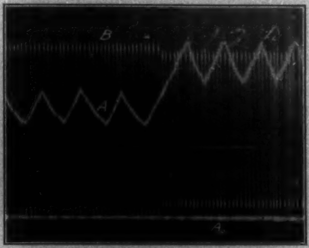

Fig. 6—Oscillographic Verification of Fig. 3, Using New Regulator

Curve A: Exciter voltage
Curve B: Alternator voltage

Consider the simple regulator shown in Fig. 8. The voltage which is to be regulated is impressed on coil *A* which is arranged to pull upward on its plunger. One end of this plunger is mechanically connected to the dashpot *B* and the other end is attached to the pivoted lever *C*. This entire lever system is adjusted by means of the weight *W* so that it is statically balanced when normal regulated voltage is impressed on coil *A*.

Fig. 7—Oscillographic Verification of Fig. 4, Using Regulator Without D-c. Coil

Curve A: Exciter voltage
Curve B: Alternator voltage

The lever system on the left comprises a coil *D*, connected to the armature terminals of the exciter, a plunger which is pulled downward by coil *D* and a pivoted lever *E*. The motion of this lever is opposed by the spring *F*. The contacts *G*, when closed, operate relays which short-circuit resistance in the exciter field circuit and, when open, insert this resistance. For simplicity, the contacts *G* are shown in the diagram to perform this function without the use of auxiliary relays.

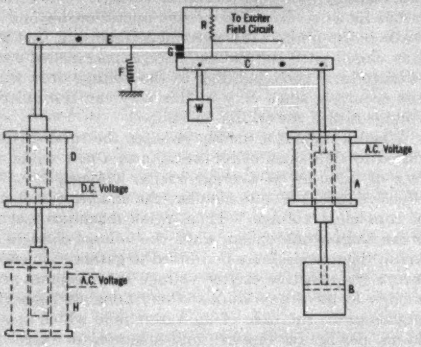

FIG. 8—SCHEMATIC DIAGRAM OF A VOLTAGE REGULATOR OF THE VIBRATING CONTACT TYPE

Assuming that the voltage impressed on coil *A* is normal, and that the lever *C* is in a given position as shown, then when the contacts are closed the resistance *R* in the exciter field circuit is short circuited and the exciter voltage increases exponentially. As it increases, the pull of coil *D* also increases and eventually becomes great enough to overcome the opposing pull of the spring, and the contacts open. The resistance *R* is thus inserted in the exciter field circuit, the exciter voltage decreases, the pull of coil *D* decreases and eventually, the spring overcomes the pull of coil *D* and the contacts close again. These operations then continue periodically at a frequency of the order of five cycles per sec. The exciter voltage then consists of periodic exponential increases and decreases as shown in Fig. 9. If the average value of this exciter voltage is just sufficient to maintain normal voltage on the alternator, the regulator is in equilibrium and lever *C* remains in the assumed position. If now a drop of alternator voltage occurs, lever *C* is no longer in equilibrium and starts to rotate in a clockwise direction. As the left end gradually rises, more and more average exciter voltage is required to balance the pull of the spring. Lever *C* will thus continue to move until the exciter voltage has increased once more to a value which will just maintain normal alternator voltage. The speed of motion is controlled by the dashpot which is necessary to give stable operation. Although the dashpot is necessary to stabilize the regulator, nevertheless it introduces sluggishness of response to changes of alternator voltage. The variation of exciter voltage immediately following a sudden drop of controlled voltage then appears as shown in Fig. 10. The effective speed of exciter build-up is then largely controlled by the characteristics of the dashpot. It is interesting to note that the dashpot causes the effective speed of build-up of exciter voltage to be modified in quite a similar manner as for a regulator which suddenly changes the ratio of time-closed to time-open following a drop in terminal voltage. The difference between the regulator described and one which suddenly changes its ratio of time-closed to time-open is thus more in degree than in principle, and neither type obtains marked increases of power above the static power limit.

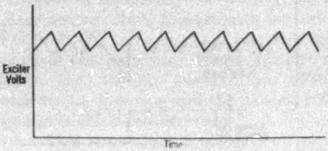

FIG. 9—VARIATION OF EXCITER VOLTAGE WITH TIME UNDER STEADY LOAD CONDITIONS

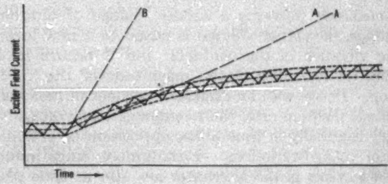

FIG. 10—CURVE SHOWING THE EFFECTIVE RATE OF CHANGE OF EXCITER FIELD CURRENT FOLLOWING A DROP OF ALTERNATOR VOLTAGE

a. Slope of Line A gives the initial rate of change when the ratio of time closed to time open of the contacts suddenly changes

b. Slope of Line B gives the rate of change when the contacts close and stay closed

When another coil *H* is added to the left hand lever system of the regulator described above, the regulated voltage being impressed on this coil, a distinct difference in operation occurs. As explained before, a definite average pull is required to overcome the force of the spring for any given position of the lever *C*. This pull is now made up of two components, one of which is a function of alternator voltage and another which is a function of exciter voltage. The exciter voltage, as before, controls the contact vibration and the total force due to both coils will appear as shown in Fig. 11. If the alternator voltage now suddenly decreases, the total pull also decreases and is no longer sufficient to overcome the counter pull of the spring and the contacts close and remain closed until an exciter voltage is obtained which, in conjunction with the reduced alternating voltage, is again sufficient to open the contacts. The characteristic of the regulator immediately following such a disturbance is as shown in Fig. 12. *Before the contacts can start vibrating again* the exciter voltage must increase to a new definite value, the magnitude of the change depending upon the magnitude of the drop of alternating voltage. Thus, immediately following a sudden change of alternator voltage, the exciter voltage is raised to a new level in one vibration of the contacts; and it occurs in one vibration regardless of the magnitude of the voltage drop. Hence, with an excitation system of reasonable voltage build-up rate, the average exciter voltage will vary essentially in time phase opposition to the alternator voltage variations. Furthermore, since induced field currents in the alternator are also in time phase opposition to the voltage variations, it follows that this excitation system furnishes exciter voltage changes in time phase with the alternator field current variation and thus compensates all or part of the *i r* drop in the field circuit. In other words, the effect is obtained of introducing negative resistance in the alternator field circuit. This phenomenon is discussed in detail in a companion paper by Mr. R. E. Doherty.

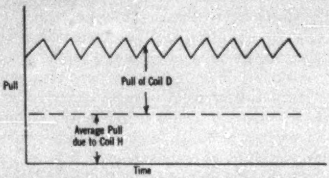

Fig. 11—Magnetic Pull on Lever *E* of Fig. 8 as a Function of Time Under Steady Load Conditions

The actual magnitude of the change of exciter voltage for a given change of alternating voltage may be controlled by suitable choice of the relative strengths of the coils *D* and *H*. The greater the strength of coil *H* compared with that of coil *D*, the greater will be the percentage increase of exciter voltage for a given change of alternator voltage.

It may be noted that the left hand lever system alone can never restore the regulated voltage to normal, although it can be made as nearly so as desired by controlling the relative strengths of the two coils. This is evident from the fact that if the voltage was restored to normal, the total pull required to open the contacts would be the same as its initial value, that is, the exciter voltage would be unchanged, but, by assumption, there is a drop in a-c. voltage for this exciter voltage. Hence the left hand lever alone cannot completely restore normal voltage. The final adjustment of voltage to normal is accomplished by the relatively slow movement of lever *C*.

## Some Requirements for Dynamic Stability

When machines are operating under conditions of dynamic stability, they are continuously beginning to fall out of step or to approach each other in phase position with resultant voltage variations which are at first of small magnitude. Any delay of the regulator response to these voltage changes at this time has a vital effect upon the performance of the system. However, the fact that a voltage regulator closes its contacts immediately following a drop of voltage, or vice versa, is not alone sufficient to permit operation beyond the static power limit. It is extremely important that they stay closed until the exciter voltage has reached a new average level corresponding to the voltage drop which has occurred, since only in this way can the inherent voltage rate of the exciter be utilized.

When a regulator merely changes the ratio of time-closed to time-open of its contacts to a new value, the rate of build-up of average exciter voltage, *i. e.*, the effective rate, becomes smaller, the smaller the change of controlled voltage. Thus, when machines start to break from synchronism, when the voltage changes are small, the machines are permitted to gather momentum before the effective exciter voltage rate becomes great enough to be of any value. Conditions are somewhat analogous to the case of an automobile which travels 20-mi. per hr. for one hr., and attempts to travel the next 20-mi. at such a speed as to average 40-mi. per hr. for the entire distance. It cannot be done.

It is also important that the controlled exciter shall have a sufficient inherent voltage rate so that a call for increased or decreased exciter voltage by the regulator is promptly followed by the change. The impulse to change the exciter voltage, although given instantly, is of little value if the exciter cannot respond.

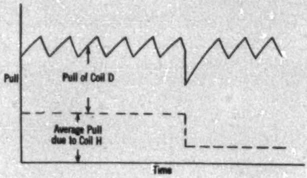

Fig. 12—Magnetic Pull on Lever *E* of Fig. 8, as a Function of Time, When the Alternator Voltage Suddenly Decreases

It should be noted, however, that sufficiently rapid response of exciter voltage does not necessarily require abnormal exciter voltage rates. Important gains in maximum power have been obtained with the most sluggish exciters obtainable when used in conjunction with a regulator of the proper characteristics. There are several factors, discussed later, which exert a decided influence on the requirements of exciter voltage rate for any given case.

Another requirement for dynamic stability is that the voltage regulator shall not cumulate such oscillations as might occur. Transmission systems, comprising synchronous machines, are ordinarily oscillatory, *i. e.*, when shaft loads are suddenly changed, the system does not arrive at its final position of equilibrium at once, but only after an oscillation. Once such an oscillation begins it may be either cumulated or damped out, depending upon the time phase characteristics of the regulator and excitation system. The proper time phase relations are obtained largely by the mechanical design of the regulator and the use of anti-hunting devices as have been used in the past.

The characteristics of an automatic voltage regulator and other elements of the excitation system do not alone determine the amount of power which can be transmitted over a system operating under dynamic stability. There are other important system characteristics which have a powerful influence on what a regulator and excitation system can accomplish in the way of increased maximum power.

One of these is the mechanical inertia of the rotating parts. The problem alone of operating above the static power limit would present much less difficulty if all machines had exceedingly large values of inertia. In this case, variations of shaft loads would produce such small values of acceleration that the changes in angular position, and therefore changes in terminal voltage, would be very slow—so slow that practically any kind of voltage regulation, including hand control, could maintain the voltages normal at all times and the maximum power would have the same value as for the case of infinite busses.

This may be illustrated by considering the analogous case of balancing on one's hand, a rod with a weight on the upper end. As the distance of the weight from the point of support is increased, the torque, for a given angular displacement from the vertical, is increased in direct proportion, but the moment of inertia is increased as the square of the distance. Hence, for any angular displacement, the angular acceleration is inversely proportional to the distance, and the necessity for very rapid response of the hand decreases. It is this difference which makes it so much more difficult to balance a toothpick than a ten-ft. rod.

Now in the case of synchronous machines, with finite values of inertia it is more difficult to maintain dynamic equilibrium; and with no inertia at all, it would be extremely difficult with practical regulators and excitation systems if other factors were not present.

One of the most important of these is damping. When machines drift apart in phase position, the terminal voltage also shifts and there is relative motion between the rotating fluxes in the machines and the rotor windings. This relative movement causes currents to be induced in the short circuited rotor windings and a torque arises which has a component proportional to this relative velocity at a given instant. Such a torque constitutes damping and causes the drift out of synchronism to occur more sluggishly than if it were not present. Increased damping action thus permits more time for the excitation system to function, and dynamic stability is thus more readily maintained.

Still another important factor exists, namely, the electromagnetic inertia of the field windings. As machines change their relative phase position, the armature current changes and tends to increase or decrease the flux linking the main field winding, depending on the nature of the current change. This change in flux linking the field winding is not instantaneous, but occurs exponentially with time, its rate of change depending on the constants of the field circuit. Thus, due to the electromagnetic inertia of the field circuit, the inherent tendency is for the field current to change spontaneously in the right direction to increase stability.

Considering the limiting case of zero resistance, the flux linking the field circuit could never change without changing the impressed voltage, and any regulator could obtain a maximum power corresponding to conditions of constant flux linking the field winding instead of constant current, *i. e.*, transient reactance would be effective for conditions where synchronous reactance is now effective.

An approach toward conditions of constant flux linkages in the field circuit can be made in different ways. Either a decrease of resistance or an increase of inductance will tend toward constant flux linkages. When this result is obtained by reducing the resistance, the transient reactance is unchanged and an increased time constant is obtained without harmful results. However, if inductance were inserted in the field circuit, the increase in transient reactance more than offsets the benefits gained by the increased time constant. For infinite inductance in the field circuit, synchronous reactance is effective at all times, since conditions of constant field current would then exist. The maximum power would then be the static power limit, by definition.

Any one of these factors, described above, may make it possible to operate machines above their static power limit. It so occurs, however, that even with all three available, the full advantage of their combined effect cannot be utilized in increasing the maximum power unless a more effective control of the excitation is available than has been in the past. In order to use these factors to the greatest advantage, a new regulator, with the features already described, has been designed. With this regulator, decisive increases in maximum power have been obtained in test. These are also given in a companion paper by Mr. R. E. Doherty.

## EFFECT OF CONSTANTS OF THE FIELD CIRCUIT

It has been pointed out that damping and electromagnetic inertia make operation under conditions of dynamic stability more easily obtained. When the resistance of the field circuit is increased, the damping torque for given values of slip, and the time constant of the field circuit, are both decreased. It would then be expected that, for a given excitation system, the maximum power would be decreased when resistance is inserted in the field circuit.

The insertion of external inductance in the field circuit, *i. e.*, increasing the leakage and transient reactances, also influences maximum power. Although field inductance increases the tendency toward constant flux linkages in the field circuit by increasing the time constant, nevertheless it also increases transient reactance which more than offsets the benefits of the increased time constant. For infinite reactance, constant field current would exist and, as already mentioned, the dynamic power limit would be identical with the static power limit.

These effects of resistance and inductance in the field circuit on maximum power have been verified by tests and the results are shown in Fig. 13.

Although it is true that the effect of increased field resistance may be counteracted by changing the regulator characteristic[4], nevertheless, it introduces more difficulties in regulator design. Furthermore, inherently low resistance, as far as it is economically obtainable, is to be preferred to artificial low resistance.

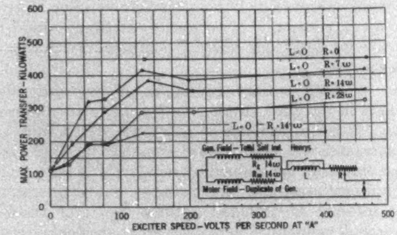

FIG. 13—RELATION BETWEEN MAXIMUM POWER AND EXCITER VOLTAGE RATE FOR DIFFERENT VALUES OF RESISTANCE AND INDUCTANCE IN THE ALTERNATOR FIELD CIRCUITS

Circuit connections as shown in Fig. 16

## SHORT CIRCUITS

Sudden disturbances, such as short circuits, result in a sudden drop in terminal voltage with a resultant loss of considerable synchronizing power for given conditions of angular displacement, fluxes, field currents, etc. Hence, at the instant a short circuit occurs, the angular displacement between the various machines begins to change and sufficient momentum may soon be acquired to cause loss of synchronism if corrective measures are not taken at once and as rapidly as possible.

Just as in the case of dynamic stability, inherent damping, inertia, and the tendency toward constant air-gap flux are favorable, their general effect being to increase the time required for breakdown to occur after a short circuit and in some cases they may, acting alone, prevent breakdown from occurring at all, if the short circuit is cleared in a reasonable time. In general, more time is permitted for excitation changes when these factors are large than when they are small.

However, such favorable factors as do exist do not seem to be sufficiently effective to allow the use of exciter voltage rates available in standard exciters, although these rates are sufficient for dynamic stability. This point is fully discussed in the companion paper by Mr. R. E. Doherty. As pointed out in that paper, the requirements of an excitation system to take care of short circuits are that the change of exciter voltage be initiated at once, and that it increase at a very rapid rate to the value which has been determined by the conditions of the particular case.

To fulfil the above requirements, the regulator must promptly close its contacts and keep them closed until the proper excitation voltage is reached, and the exciter voltage rate must be relatively high. Moreover, the regulator must not distinguish between phases—*i. e.*, it must act the same way regardless of the phase on which the short circuit occurs. Regulators which will accomplish this are commercially available.

If the a-c. voltage change is non-symmetrical, *i. e.*, different on the different phases, as in the case of single-phase short circuits, the response of a regulator controlled from one phase only will be different, depending upon the phase to which it is connected. In order that the regulator action shall be the same, regardless of the phase which is short circuited, various schemes are available. One of them provides an actuating a-c. voltage for the regulator which is proportional to the positive phase sequence component of the 3-phase line voltage. Another scheme, which is very effective, is to replace the usual a-c. voltage coil of the regulator in Fig. 8 by a small polyphase stationary torque motor, the shaft of which replaces the pivot of the right hand lever. A dead short circuit on any phase then causes the torque of this motor to become zero, and therefore maximum effectiveness in increasing the exciter voltage is obtained.

## TEST RESULTS

During the last few years, much valuable information has been obtained and many question have been answered by extensive factory tests, and also field tests. The latter will appear in a forthcoming paper. The first tests, in which the new regulator was used, were made on small 3.75 kw. machines with an interconnecting transmission line. The motor and generator were identical, each having a direct synchronous reactance 1.55 and a quadrature reactance 0.30 on the basis of 10 kv-a. at 100 volts, line to line. On this same basis, the reactance of the interconnecting line was 1.0 and the resistance was 0.05. The diagram of connections for this system is shown in Fig. 14. A shunt motor drove a synchronous generator which delivered power over a transmission line to a synchronous motor. This motor drove a shunt generator which could be loaded by means of a resistance across its terminals. The excitation was furnished by a 3-kw., 1800-rev. per min., 125-volt shunt wound exciter. During these tests self excitation and separate excitation with different voltages impressed on the field circuit of the exciter were used. In this way, exciter voltage rates ranging from 50 to 400 volts per sec. could be obtained.

---

[4] As has been pointed out, a new regulator is available which has the effective characteristic of introducing negative resistance in the field circuit, the value of this negative resistance depending on the regulator constants.

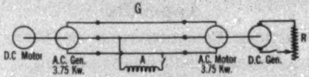

FIG. 14—SCHEMATIC DIAGRAM OF THE SMALL TRANSMISSION SYSTEM USED IN THE TESTS

The first tests on this system were to determine the static power limit. For various values of fixed excitation on the motor and generator, power-voltage curves were taken and the results are shown in Fig. 15. From the locus of maximum power points, the static power limit for any operating voltage may be determined. The operating voltage used throughout these tests was 110 volts, giving a static power limit of 6.1 kw. The maximum power of the line alone, *i. e.*, with infinite busses at each end, is neglecting resistance 12.0 kw.

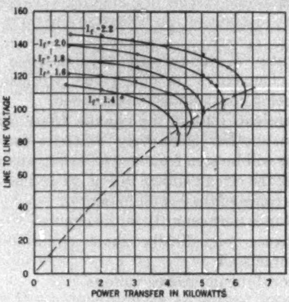

FIG. 15—POWER-VOLTAGE CURVES BY CALCULATION AND TEST

Two AHI-4-3.75-1800-110-volt synchronous machines connected through a transmission line. Excitation on motor and generator held constant at different values

Tests were then made to determine the effect of exciter voltage rate on maximum power when commercial regulators, including both the types with d-c. coil and without d-c. coil, were used. The results showed that the maximum power was practically independent of exciter voltage rate for these regulators, the same power, *i. e.*, 7 kw., being obtained with various commercial regulators for widely different values of exciter voltage rate. It is interesting to note that this same value of power, slightly above the static power limit was also obtained by hand control. However, when the new regulator was used, the difference became apparent at once. The maximum power was increased immediately to 10 kw. and after careful adjustment this was increased to 11 kw., or a gain of approximately 60 per cent. When it is considered that the possible gain, assuming infinite busses at each end, is 70 per cent, the results are seen to contain elements of great practical importance.

The system was also shown to be remarkably stable to sudden shocks. A reactor, *A*, whose reactance was of such a value as to take a current of the order of normal current on the basis of 10 kv-a. at 100 volts, could be repeatedly connected across the terminals, and disconnected, and the system remained in synchronism, even when carrying a load of 9 kw. or 30 per cent more than standard regulators could obtain under steady conditions.

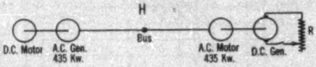

FIG. 16—DIAGRAM FOR LARGER TRANSMISSION SYSTEM USED IN TESTS

Machine Ratings:
Alternator and Motor: TS-435-1200-4000/2300 volts
D-c. Motor and Generator: MPC-6-300-1200-250/275 volts
Exciter: MP-4-17-700-250 volts—68 amperes

Question then arose concerning the difference that might be obtained using a larger system. Therefore another system, shown in Fig. 16, was set up, using machines having a rating of 435 kv-a. at normal voltage, *i. e.*, at 4000 volts. The synchronous reactance on this basis was 1.18 and the quadrature reactance was 0.62. For excitation purposes, a separately excited, 4-pole, 20 kw., 1200-rev. per min., 125-volt exciter was used in conjunction with various types of voltage regulators. During these tests, the machines were operated at reduced voltage, *i. e.*, 2200 volts, in order that the d-c. machines should not be too heavily overloaded. At this reduced voltage, the static power limit, as determined by power voltage curves taken under conditions of constant excitation, was 120 kw. With standard commercial regulators and with hand control, a maximum power of 180 kw. was obtained, this power being practically independent of the exciter voltage rate. The new regulator increased this power to 480 kw., approximately an increase of 170 per cent, *i. e.*, the maximum power was almost tripled.

Tests were also made on this system under short-circuit conditions. The short circuit comprised a resistance of 47 ohms, or 1.28 on the basis of 435 kv-a. at 4000 volts. This partial short circuit was left on for 0.8 sec. and under these severe conditions, the machines remained in synchronism when carrying an initial load of 330 kw. which is almost twice as much as could be carried by the system with standard regulators under steady conditions.

At a later date a similar system was set up, using machines of the same rating but having a slightly higher value of synchronous impedance, *i. e.*, 1.27 on the basis of 435 kv-a. at 4000 volts. These machines, as in previous tests, were operated at reduced voltage, in this case, 2240 volts, and the power voltage curves under conditions of constant excitation are given in Fig. 17.

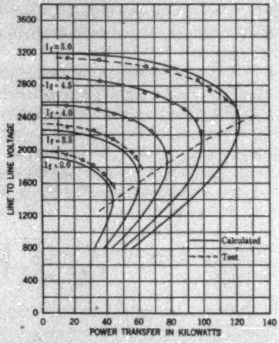

FIG. 17—POWER-VOLTAGE CURVES BY CALCULATION AND TEST

Two TS-6-435-1200-4000/2300-volt synchronous machines connected to the same bus. Excitation on motor and generator held constant at different values

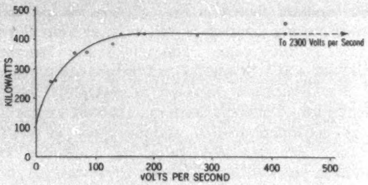

FIG. 18—MAXIMUM POWER AS A FUNCTION OF THE EXCITER VOLTAGE BUILD-UP RATE FOR THE TEST SET-UP OF FIG. 16, USING NEW REGULATOR

The static power limit at 2240 volts is thus 110 kw. When standard automatic voltage regulators were used, as well as hand control, the maximum power under steady load conditions was of the order of 200 kw. The new regulator with the same excitation system increased the maximum power to 415 kw.

Previous tests had indicated that extremely high exciter voltage rates were unnecessary for increasing the maximum power under steady load conditions. Tests were made on this new system to verify this and the results of the tests are shown in Fig. 18. It may be noted that large gains in maximum power are obtained with this new regulator, using exciter voltage rates readily obtainable in standard exciters.

The effects of resistance and inductance inserted in the field circuit were also determined. As previously pointed out, increasing these constants should make it more difficult to obtain large gains in maximum power. These conclusions are justified by the results shown in Fig. 13.

## Appendix

### THEORETICAL CONSIDERATIONS OF VIBRATING CONTACTS

It has been explained that a vibrating contact voltage regulator controls the average exciter voltage by maintaining different ratios of the time that the contacts are closed across a resistance in the exciter field circuit to the time that they are open. Two methods are available for changing from one exciter voltage to another. The contacts may be closed and kept closed until the new average voltage is obtained, vibration being then resumed at a new ratio of time-close to time-open which will maintain the new exciter voltage; or, the ratio of time-closed to time-open may be suddenly changed to its new value, vibration of the contacts being continuously maintained.

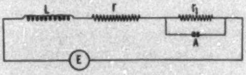

FIG. 19—ELECTRIC CIRCUIT IN WHICH THE AVERAGE CURRENT IS CONTROLLED BY VIBRATING CONTACTS

The transient during the change from one exciter voltage to another is entirely different for the two methods as will be seen from the following analysis.

Consider the circuit shown in Fig. 19 and let

$L$ = inductance of the circuit in henrys.

$r$ = resistance permanently in the circuit.

$r_1$ = resistance periodically short circuited by the contacts, $A$.

$E$ = the constant impressed voltage.

$r_2 = r + r_1$

When the contacts are closed, the differential equation for the circuit is

$$L \frac{d\,i}{d\,t} + r\,i = E \tag{1}$$

The solution of equation (1) is

$$i = \frac{E}{r} - \left(\frac{E}{r} - i_1\right) e^{-\alpha(t - t_1)} \tag{2}$$

where $i_1$ = the current at the instant the contacts close.

$$\alpha = \frac{r}{L}$$

$t_1$ = time at which the contacts close.

When the contacts are open the differential equation is

$$L\frac{di}{dt} + r_2 i = E \qquad (3)$$

and the solution is

$$i = \frac{E}{r_2} - \left(\frac{E}{r_2} - i_2\right)\epsilon^{-\beta(t - t_2)} \qquad (4)$$

where $i_2$ = the current at the instant the contacts open.

$$\beta = \frac{r_2}{L}$$

$t_2$ = the time at which the contacts open.

When the contacts are operating under sustained conditions, the final current of equation (**2**), *i. e.*, at $t = t_2$, must equal the initial current of equation (**4**), and also the final current of equation (**4**), *i. e.*, at $t = t_3$, must equal the initial current of equation (**2**).

Hence $$i_{2s} = \frac{E}{r} - \left(\frac{E}{r} - i_{1s}\right)\epsilon^{-\alpha(t_2 - t_1)} \qquad (5)$$

$$i_{1s} = \frac{E}{r_2} - \left(\frac{E}{r_2} - i_{2s}\right)\epsilon^{-\beta(t_3 - t_2)} \qquad (6)$$

where

$i_{2s}$ = the final current with the contacts closed and the initial current with the contacts open, under sustained conditions.

$i_{1s}$ = the initial current with the contacts closed and the final currents with the contacts open.

Evidently, $t_2 - t_1$ is the time during which the contacts are closed in each vibration and $t_3 - t_2$ is the time that they are open. Letting

$$t_2 - t_1 = t_c = \text{time closed} \qquad (7)$$

$$t_3 - t_2 = t_0 = \text{time open} \qquad (8)$$

equations (**5**) and (**6**) become

$$i_{2s} = \frac{E}{r} - \left(\frac{E}{r} - i_{1s}\right)\epsilon^{-\alpha t_c} \qquad (9)$$

$$i_{1s} = \frac{E}{r_2} - \left(\frac{E}{r_2} - i_{2s}\right)\epsilon^{-\beta t_o} \qquad (10)$$

Solving these simultaneous equations for $i_{2s}$ and $i_{1s}$

$$i_{1s} = E\left\{\frac{\frac{1}{r_2} - \frac{1}{r_2}\epsilon^{-\beta t_o} + \frac{1}{r}\epsilon^{-\beta t_o} - \frac{1}{r}\epsilon^{-(\alpha t_c + \beta t_o)}}{1 - \epsilon^{-(\alpha t_c + \beta t_o)}}\right\} \qquad (11)$$

$$i_{2s} = E\left\{\frac{\frac{1}{r} - \frac{1}{r}\epsilon^{-\alpha t_c} + \frac{1}{r_2}\epsilon^{-\alpha t_c} - \frac{1}{r_2}\epsilon^{-(\alpha t_c + \beta t_o)}}{1 - \epsilon^{-(\alpha t_c + \beta t_o)}}\right\} \qquad (12)$$

Equations (**11**) and (**12**) determine the minimum value, $i_{1s}$, and the maximum value, $i_{2s}$, of the exciter field current under sustained conditions. The variation of current between these limits is given by equations (**2**) and (**4**). The current in the circuit, under sustained conditions, then has the form shown in Fig. 20.

The average current under sustained conditions is obtained as follows:

The area under the current curve during one interval when the contacts are closed is, from equation (**2**),

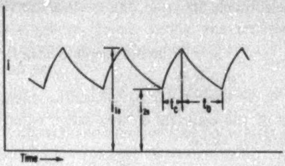

FIG. 20—CURRENT IN THE CIRCUIT OF FIG. 19 AS A FUNCTION OF TIME

$$A_c = \int_{t=t_1}^{t=t_2}\left\{\frac{E}{r} - \left(\frac{E}{r} - i_1\right)\epsilon^{-\alpha(t - t_1)}\right\}dt \qquad (13)$$

$$= \frac{E}{r}t_c - \frac{E}{r\alpha} + \frac{E}{r\alpha}\epsilon^{-\alpha t_c} + \frac{i_1}{\alpha}(1 - \epsilon^{-\alpha t_c}) \qquad (14)$$

The area of the current curve during one interval when the contacts are open is, from equation (**4**),

$$A_0 = \int_{t=t_2}^{t=t_3}\left\{\frac{E}{r_2} - \left(\frac{E}{r_2} - i_2\right)\epsilon^{-\beta(t - t_2)}\right\}dt \qquad (15)$$

$$= \frac{E}{r_2}t_0 - \frac{E}{r_2\beta} + \frac{E}{r_2\beta}\epsilon^{-\beta t_o} + \frac{i_2}{\beta}(1 - \epsilon^{-\beta t_o}) \qquad (16)$$

The average current is then the sum of (**14**) and (**16**) divided by one period of the contacts, $t_0 + t_c$, or

$$i_{ave} = \frac{E\left\{\frac{t_c}{r} + \frac{t_0}{r_2} - \frac{1}{r\alpha} - \frac{1}{r_2\beta} + \frac{1}{r\alpha}\epsilon^{-\alpha t_c} + \frac{1}{r_2\beta}\epsilon^{-\beta t_o}\right\} + \frac{i_1}{\alpha}(1 - \epsilon^{-\alpha t_c}) + \frac{i_2}{\beta}(1 - \epsilon^{-\beta t_o})}{t_0 + t_c} \qquad (17)$$

When equations (**11**) and (**12**) are substituted in (**17**) the average sustained current is,

$$i_{ave} = E\left\{\frac{\frac{t_c}{r} + \frac{t_0}{r_2}}{t_0 + t_c} - \frac{L}{t_0 + t_c}\left(\frac{r_2 - r}{r_2 r}\right)^2\right.$$

$$\left.\frac{(1-\epsilon^{-\beta t_o})\,(1-\epsilon^{-\alpha t_c})}{(1-\epsilon^{-(\alpha t_c+\beta t_o)})}\right\} \qquad (18)$$

Since $\frac{1}{r}$ is the conductance of the circuit when the contacts are closed, and $\frac{1}{r_2}$ is the conductance when the contacts are open, the average current, when $L = 0$, is

$$i_{ave} = E \text{ (average conductance)} \qquad (19)$$
$$L = 0$$

When L is very large or when the frequency of vibration of the contacts is very large, equation (**18**) approaches the value

$$i_{ave} = \frac{E}{\dfrac{r\,t_c + r_2\,t_0}{t_0 + t_c}} \qquad (20)$$

$L = \infty$ or $t_0 + t_c = 0$

or the average current, for these conditions, is determined by the average resistance. In most practical cases, the combined effects of inductance and contact frequency will be sufficiently great to make equation (**20**) a good working approximation.

The manner in which the average sustained current changes from one average value to another is of importance in the problem of maximum power. When the change is initiated by suddenly changing the ratio of the time that the contacts are closed to the time that they are open, the new sustained value of current is not attained in one vibration of the contacts but only after a relatively long transient. For one closing of the contacts at the time $t_1$, the initial current is $i_1$. The current increases to $i_2$ determined by equation (**2**), and $i_2$ is the initial current when the contacts open. After they open, the current decreases to a new value

$$i_3 = \frac{E}{r_2} - \left(\frac{E}{r_2} - i_2\right)\epsilon^{-\beta t_0} \qquad (21)$$

determined by equation (**4**), and $i_3$ is the initial current when the contacts again close. Under sustained conditions, $i_3 = i_1$, but when the ratio of $t_c$ to $t_0$ is suddenly changed, $i_3 \neq i_1$ until the new sustained values are reached.

During the transient period, the difference between $i_1$, for a given closing of the contacts, and its final sustained value, $i_s$, given by equation (**11**), is

$$i_{1s} - i_1 =$$
$$E\left\{\frac{\dfrac{1}{r_2} - \dfrac{1}{r_2}\epsilon^{-\beta t_o} + \dfrac{1}{r}\epsilon^{-\beta t_o} - \dfrac{1}{r}\epsilon^{-(\alpha t_c+\beta t_o)}}{(1-\epsilon^{-(\alpha t_c+\beta t_o)})}\right\}$$
$$- i_1 \qquad (22)$$

The difference between the new sustained value, $i_{1s}$, and $i_3$, one cycle of vibration later, is

$$i_{1s} - i_3 = E\,\epsilon^{-(\alpha t_c+\beta t_o)}$$
$$\left\{\frac{\dfrac{1}{r_2} - \dfrac{1}{r_2}\epsilon^{-\beta t_o} + \dfrac{1}{r}\epsilon^{-\beta t_o} - \dfrac{1}{r}\epsilon^{-(\alpha t_c+\beta t_o)}}{(1-\epsilon^{-(\alpha t_c+\beta t_o)})}\right\}$$
$$- i_1\,\epsilon^{-(\alpha t_c+\beta t_o)} \qquad (23)$$

The ratio obtained by dividing (**23**) by (**22**) is

$$d = \epsilon^{-(\alpha t_c+\beta t_o)} \qquad (24)$$

This is the value of the decrement of the minimum current values per cycle of vibration of the contacts. Since this ratio is constant, the envelope of the minimum current values is exponential in form, and the current, for any instant at which the contacts close, is

$$i_1 = i_{1s} - (i_{1s} - i_{10})\,\epsilon^{-\left(\frac{\alpha t_c+\beta t_0}{t_c+t_0}\right)t} \qquad (25)$$

The decrement factor of (**25**) is

$$\sigma = \frac{\alpha\,t_c + \beta\,t_0}{t_c + t_0} = \frac{r\,t_c + r_2\,t_0}{L\,(t_c + t_0)} = \frac{\text{average resistance}}{L} \qquad (26)$$

It is interesting to note that although the sustained average current is determined by the average conductance when $L$ is zero, [equation (**19**)], by the average resistance when $L = \infty$, [equation (**20**)] and by some intermediate value when the inductance is finite, nevertheless, the time constant during a transition period is always a function of average resistance.

It can be shown that the maximum current peaks and average current also vary according to the same exponential law. Hence, when the ratio of time-closed to time-open is suddenly changed, the average current changes from its initial sustained value to its final sustained value according to equation (**27**).

$$i_{ave} = i_s - (i_s - i_0)\,\epsilon^{-\frac{\text{average resistance}}{L}t} \qquad (27)$$

where $i_s$ is the final and $i_0$ the initial sustained average current. During this transient, the current will appear as shown in Fig. 10.

Inspection of Fig. 10 shows how much slower the exciter field current builds up when the contacts open and close during the change in field current than when they close and remain closed until the exciter field current has reached its new value. With the slower scheme, the effective rate of change of exciter field current is given by the slope of the exponential curve through the current peaks, *i. e.*, by the slope of line $A$; whereas, if the contacts close and stay closed until the new average value of exciter field current is reached, the effective rate of change of field current is given by the slope of line $B$. The new regulator functions in this way and the marked results obtained with it are largely due to this characteristic.

The superiority of this principle may be brought out by the following example.

Let Fig. (21) represent the saturation curve and field characteristic of an exciter which is controlled by a regulator whose contacts close and open during the change in field current. Assume that the contacts are vibrating 5-times per sec. and that the initial time-closed and time-open intervals are

$$t_c = 0.04 \text{ sec.}$$
$$t_0 = 0.16 \text{ sec.}$$

Then the average field current, determined by equation (**21**), is 3.67 amperes, the corresponding exciter voltage, from Fig. 21 is 110 volts, and the ratio of time-closed to time-open is $\frac{t_c}{t_0} = 0.25$.

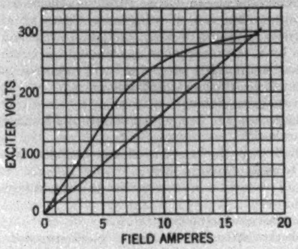

Fig. 21—Saturation Curve and Field Characteristic of the Exciter Used in the Numerical Example

Voltage impressed on exciter field, 500 volts. Resistance of field winding, 16.67 ohms. External resistance, 166.67 ohms

When the ratio of time-closed to time-open is suddenly increased to some new value, the initial rate of change of average exciter field current, can be determined by means of equations (**18**) and (**27**). The rate of change of average exciter voltage may then be obtained from Fig. 21. The curve in Fig. 22 shows the initial rate of change of average exciter voltage in volts per second when the ratio of time-closed to time-open is changed.

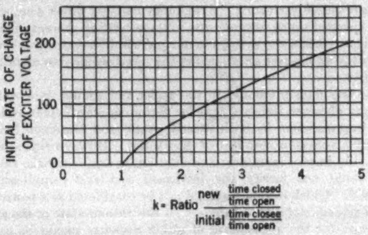

Fig. 22—Rate of Change of Average Exciter Voltage as a Function of Changes of the Ratio of Time-Closed to Time-Open of the Vibrating Contacts

It will be noticed that, as the change in this ratio becomes smaller, the effective rate of change of exciter voltage also becomes smaller, approaching zero as a limit. Hence at incipient breakdown, where the changes of this ratio are small, a regulator which closes and opens its contacts during the change in field current is very ineffective and the synchronous machines will acquire some momentum on their way out of synchronism before the regulator becomes very effective. It is thus apparent that the machines are allowed to get under way, out of synchronism which is usually fatal as far as operation under conditions of dynamic stability is concerned.

If, with *the same exciter*, a regulator is used which keeps its contacts closed during the transient, the initial rate of change of average exciter voltage becomes *438 volts per sec.*

Therefore, a regulator which continues to vibrate its contacts during a change of exciter field current causes the apparent or effective speed of exciter build-up to be markedly less than its inherent speed.

In many cases, the necessity for abnormal exciter voltage rates may be overcome by using the new regulator which takes advantage of the inherent exciter speed at all times.

## Discussion

**C. A. Powel:** The problem of quick-response excitation in its relation to stability is one of great importance, and one in which I have been much interested. In fact, I believe my paper prepared for the "High Voltage Conference" at Paris last year, and later published in the *Electric Journal* of April 1927, was the first one devoted exclusively to quick-response excitation. Mr. Doherty's paper is interesting and valuable in itself, and also because it disposes of a controversy over a major question in the general problem of stability. He refers to a heretofore unexploited zone of artificial stability, and it may be interesting to review the work previously done in this zone.

At the A. I. E. E. Mid-Winter Convention in 1924, E. B. Shand[1] suggested that operation in the zone of artificial stability might be possible if we could change the excitation within the synchronous machine quickly enough. The idea was further developed in the course of our work on high voltage transmission, and at the Mid-Winter Convention in 1925, Messrs. Fortescue and Wagner[2] were able to amplify considerably Mr. Shand's ideas. In September 1925, at the Seattle Convention, Mr. Fortescue[3] definitely proposed an increased speed of excitation obtained by regulator control as a means of increasing the stability of a transmission system, and Mr. Doherty and his colleagues specifically disagreed with him, maintaining the position that quick response, if it was to be obtained by means of a voltage regulator, would not make it possible to carry a constant load significantly greater than with hand control. Mr. Doherty expressed himself as being of the opinion that improvements by compensation rather than by regulation were a more hopeful field for future development. Such improvements have been suggested in the past and involve either a series exciter or compounding by means of rectifiers or converters.

At the Mid-Winter Convention in 1926, Messrs. Evans and Wagner[4] presented a paper which summarized the exploitation, by them and their colleagues, of the range of operation of synchronous machines beyond the static limit as set by constant excitation, both with steady loads and under transient conditions. At the time, Mr. Doherty and Mr. Nickle again asserted that the only function of the regulator was to increase automatically the excitation as the load is applied, the actual load limit being the same as for hand control; whereas Messrs. Evans and Wagner described in their closing discussion tests made at Pittsburgh in 1925. The tests were made with an artificial line having 100 per cent reactance based on the normal rating of the machines, and using a standard Westinghouse vibrating regulator. With this combination, a substantial increase over the static limit was transmitted over this miniature system.

---

[2] A. I. E. E. Trans., 1925, Vol. XLIV, pp. 98-101.

[3] *Transmission Stability,* C. L. Fortescue, A. I. E. E. Trans., 1925, Vol. XLIV, p. 984.

[4] *Studies of Transmission Stability,* A. I. E. E. Trans., 1926, Vol. XLV, p. 51.

In one of the subsequent tests described by Mr. Doherty in the paper under discussion, he obtained four times the static limit of the system with a set-up consisting of a generator and motor on a common bus with a common exciter and regulator. Now with ideal excitation and neglecting losses and saturation, the theoretical power limit of such a set-up would be infinity; whereas with a set-up consisting of a generator and motor connected by a transmission line, the stability limit is the power limit of the line itself, which is finite. The tests which Mr. Doherty reports, using an artificial line and independent control of the sending and receiving machines, give results higher than the tests made in Pittsburgh in 1925, but the latter were made with a view of establishing the facts, and not of finding the ultimate limit.

The tests are interesting, but I question if they are of the practical value that the paper implies. The true power limit of a system under present-day conditions is defined by its stability under transient conditions. Those who are operating transmission systems know that when the two ends of a system pull apart, they do so at times of a disturbance, and not as a result of slowly added load. Now for transient conditions, any a-c. control regulator, such as the Westinghouse regulator, that closes its contacts promptly and keeps them closed until the a-c. voltage is back to approximately normal, is suitable. After the regulator has closed its contacts, the recovery of the a-c. voltage is a function of the response of the exciter and generator.

Moreover, operating a system with steady loads in the zone of artificial stability as suggested, requires that the rotors of the generating units be worked at very high values of excitation, and it may be more desirable, either to increase the static limit itself by reducing the reactance of the generators, or to supply the excitation at more appropriate locations along the transmission system, as advocated in the Baum system of transmission using intermediate synchronous condensers.

**R. D. Evans:** Concerning the relation of excitation to stability, there are, as Mr. Doherty points out, two distinct problems involved:

1. The use of excitation systems to increase transient limits of power systems.

2. The use of excitation systems to increase the steady load limits of power systems.

The question naturally arises as to the relative importance of these two uses of excitation systems. This depends, of course, on whether the static limit or the transient limit is the criterion for establishing the permissible loading of the power system. The oscillographic records of operating experiences on the Southern California Edison Company system, given in the paper by Messrs. Wood, Hunt, and Griscom, presented at the Pacific Coast Convention of the A. I. E. E. last September, have established that the transient limit is the more important. Ignoring those cases involving low excitation due to line-charging condition, very small ties, insufficient frequency-changer ties, and so on, there is only one case on record where the static limit of a large power transmission system has been exceeded and that case occurred under very abnormal operating conditions. Thus one must conclude that the use of excitation systems to increase transient stability limits is the immediate problem while the increase in static limit is of less pressing nature.

Now I wish to stress the fact that considerations of transient limits have been controlling in the acceptance and adoption of quick-response excitation. Quick response was not made possible by the introduction of any new regulator, as its advantages can be obtained with existing forms of a-c. regulators. The recognition of the interest in this method of increasing the transient limit is evidenced by the fact that while the first order for such apparatus was placed during 1926, the scheme has been so widely adopted that the Westinghouse Company alone has received orders for quick-response excitation systems for about one million kv-a. of synchronous machines.

As to the requirements of excitation systems for increasing the transient limits, the most important are:

For the voltage regulator:

1. It shall close the contacts promptly upon a demand for increased excitation.

2. It shall keep the contacts closed until the a-c. voltage is restored to an appropriate value.

3. It shall possess the necessary anti-hunting features.

For the exciter:

It shall possess quick response.

Mr. Doherty attempts to define quick-response systems in terms of exciter characteristics, that is, in terms of volts per second. Such a definition, however, is not fundamental to quick response to increase stability limits of power systems. Any excitation system (which, of course, includes the regulator as well as the exciter) which is sufficiently quick to make an important change in the excitation voltage before the synchronous machine has had time to swing to a dangerous angle, beyond which recovery would be doubtful, is quick response. Or, considered from the standpoint of the fluxes in the synchronous machine, any excitation system that is quick enough to prevent a significant reduction in flux interlinkages due to demagnetizing armature current, as from a short circuit or other system disturbance, is quick response.

As a result of stability studies it has been established that a system will reach a critical point in its oscillation in something of the order of three-quarters of a second after the initiation of a disturbance, so that any corrective action, to be effective, must be made in less time than that. This requires a quicker exciter response than was used prior to the introduction, by us, of quick-response excitation. Previously exciters which were slow were speeded up to improve the voltage settling characteristics; that is, to restore the voltage to normal within a reasonable time; but not to any degree approaching the speed required to maintain stability.

The test data presented in the paper and similar data which we have obtained indicate that for certain applications considerable improvement in both steady static and transient limits result by increasing response of the exciter. However, in certain cases, the improvements in stability limits are extremely small and would not justify the increased cost and complication incurred. Quick response should not be considered as a panacea for all system stability troubles. In the present state of the art, each case for the application of quick response should be considered on its own merits.

**J. H. Ashbaugh:** The description of the exciter rheostatic regulator might give one the impression that this regulator is, if sensitive, always in a state of vibration. This is not true below the region of the static-state limit and I assume that Messrs. Nickle and Carothers did not intend to give this impression. The vibrating regulator will not maintain voltage much closer than 0.5 per cent due to imperfection of contacts. This imperfection of contacts is not present in the exciter rheostatic regulator so that it is just as sensitive as the vibrating regulator.

When transient stability is to be considered the exciter rheostatic regulator short circuits the exciter field rheostat the same as a vibrating regulator, which is in my opinion all any regulator can do for the condition.

Another feature which I should like to emphasize is the anti-hunting device. The hunting associated with the type *D* regulator is probably due to improper adjustment rather than the particular form of anti-hunting device as evidenced by tests. Messrs. Nickle and Carothers state that "The proper time-phase relations are obtained largely by the mechanical design of the regulator and the use of anti-hunting devices as have been used in the past." I am somewhat inclined to this point of view and believe that the particular anti-hunting device used in this new regulator is but one of several that would be found satisfactory.

From tests which I have conducted I do not believe that the results with the type *D* regulator as outlined in Mr. Doherty's paper are representative of this regulator. It has been my experience that greater gains than shown were obtained with an increase in volts per second of the exciter. There are several features of importance with regard to adjustment of this regulator. These have an important bearing when steady-state limit as well as transients are considered.

**C. A. Adams:** The substance of the discussion thus far is to the effect that other regulators are just as satisfactory for the control of transient instability and that there is no need of control for continuous instability, owing to the fact that synchronous machines are not continuously operated in the unstable zone.

Concerning the operation of other regulators under conditions of transient instability, I cannot speak with authority, but I do know that this particular regulator does operate and is operating to protect against transient instability.

I cannot agree with the opinion that nothing is to be gained by a regulator which will enable synchronous machines to operate continuously in or near to the unstable zone and for the following reasons:

In the early days when alternators were practically all of the low-speed multipolar type, very close inherent regulation was specified; so close, in fact, that the armature short-circuit ratio was often as high as from 3-to-5, or even 6. Moreover, with the type of machine then prevalent, this high short-circuit ratio did not constitute any considerable handicap to the designer. However, the whole situation was changed with the advent of the high-speed turbo alternator, where the limit of capacity is determined by the maximum allowable peripheral current density on the rotor. This point will be more readily appreciated from the vector diagram, Fig. 1 herewith. This is a simplified magnetomotive force diagram where *F* represents the field magnetomotive force, *A* the equivalent armature magnetomotive force proportional to the armature current, and *R* the resultant or reluctance magnetomotive force sufficient to produce a flux, the cutting of which by the armature conductors will generate the terminal voltage, ohmic drop in the armature being neglected.

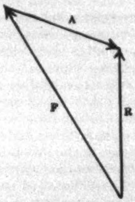

Fig. 1

The short-circuit ratio is approximately equal to $R/A$. For a given machine *F* is a measure of the peripheral current density (ampere-conductors per inch of periphery) on the rotor, and *A* of the peripheral current density on the stator.

Owing to tooth contraction on the rotor and to the requirements of mechanical strength of the teeth, the space available for copper per inch of periphery is absolutely limited, and hence the peripheral current density of the rotor. This is not the case on the stator, as there is no practical limit to the slot depth.

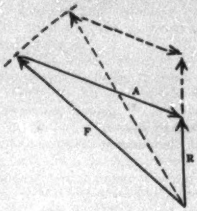

Fig. 2

Thus the real limit to the peripheral current density on the stator is the peripheral current density on the rotor and the maximum allowable ratio between the two; that is, between *A* and *F* in the diagram. The larger this ratio with the limiting value of *F*, the higher will be the possible rating and capacity of a machine of given air-gap dimensions; or, to put it in another way, for a smaller armature short-circuit ratio, which means a lesser inherent stability, the armature peripheral current density and *A* in the diagram can be larger for the same limiting value of *F*. This is shown in Fig. 2, herewith, in which Fig. 1 is reproduced in dotted lines and the diagram for the new machine of higher rating is shown in solid lines. *F* is the same for both of these machines. *A* is considerably larger for the new machine with the lower short-circuit ratio and the lesser inherent stability. *R* has been reduced, which simply means a shorter air-gap.

It is thus possible to increase the output of turbo generators with given length and rotor diameter, by shortening the air-gap and increasing the peripheral current density and copper on the armature.

The only reason why this has not been done before is because the resulting reduction in inherent stability was looked upon as dangerous. If, however, reliable regulators can be provided which will eliminate the danger from the reduction of inherent stability, I can see no reason why a considerable increase in capacity cannot be obtained at very small cost.

Therefore, a regulator which will accomplish this result certainly constitutes a real advance in the art of power generation and transmission.

**R. H. Park:** One of the most interesting results shown in the papers is the large difference between the operation of the new regulator, and the operation of the regulator without d-c. coil. Thus the data show that under steady load conditions the maximum power which could be carried, under the test conditions, was as follows:

| | |
|---|---|
| New regulator | 415 kw. |
| Regulator without d-c. coil | 225 kw. |

Subsequent tests with different adjustments indicated improved operation of the latter regulator. The results of these tests were as follows:

(A) Dynamic limit, steady load, two machines tied directly together.

| | Maximum power transient possible with stability |
|---|---|
| New regulator* | 415 kw. |
| Regulator without d-c. coil (best adjustment) | 259 kw. |
| Hand control (fixed excitation) | 110 kw. |

(The exciter speed used in connection with tests was approximately 250 volts per sec. It was found that increasing the speed of excitation did not improve the operation.)

(B) Same as (A) except shunt load of 124 kv-a. at 0.124 power factor.

| | Maximum motor load possible with stability |
|---|---|
| New regulator | 461 kw. |
| Regulator without d-c. coil (best adjustment) | 317 kw. |
| Hand control (fixed excitation) | 173 kw. |

(C) Same as (A) but machine separated by model 250-mile line.

| | Maximum motor power possible with stability |
|---|---|
| New regulator | 105 kw. |
| Regulator without d-c. coil | 98 kw. |
| Hand control (fixed excitation) | 67 kw. |

(D) Same as (C) but shunt load of 62-kv-a. at 0.12 power factor at motor end.

| | Maximum motor power possible with stability |
|---|---|
| New regulator | 88 kw. |
| Regulator without d-c. coil | 82 kw. |
| Hand control (fixed excitation) | 57½ kw. |

(E) Same as (A) but machines separated by a 500-mile line:

| | Maximum power possible with stability |
|---|---|
| New regulator | 59 kw. |
| Regulator without d-c. coil | 59 kw. |
| Hand control (fixed excitation) | 43 kw. |

(F) Different machines separated by a reactance equal to 52 per cent of machine synchronous reactance, dynamic limit steady load.

| | Maximum power possible with stability |
|---|---|
| New regulator | 63 kw. |
| New regulator with two torque motors instead of one torque motor and one a-c. coil | 63 kw. |
| Regulator without d-c. coil | 51 kw. |
| Hand control (fixed excitation) | 38 kw. |

The result of these tests is to confirm definitely the fact of an essential difference in operation between the two regulators; that is, to confirm one of the general theses of the papers that the new regulator in general possesses special characteristics particularly fitting it for controlling the operation of synchronous machines under conditions where dynamic stability is at a premium. This difference, however, as well as the gain which the regulator makes possible over hand control, diminishes as the length of line increases. The variation of dynamic limit of the two regulators, with length of intermediate line, is shown in Fig. 3 herewith. It will be seen from the figure that for lines of ordinary length the relative advantage of the new regulator is considerable.

After it is clear that there is a gain, it may be enquired whether these gains obtain in practise, or whether they apply to shop tests only. This point has not been completely explored yet. Experience has shown that the differential between the operation of the new regulator and the regulator without the d-c. coil decreases somewhat as the size of the machines tested increases. Therefore one difference which may be anticipated is that in the case of large machines this differential will be reduced.

Another difference is that in the tests made saturation was not present. Saturation, because it of itself tends to improve stability, reduces to some extent the gain which the regulator can accomplish.

Next it may be enquired where these gains in dynamic stability will be realizable. Of course, in most cases maximum power is not, as yet, felt as a limitation to normal operation. On the other hand, there are cases where the limitation of maximum power is encountered under normal conditions. These are in connection with power transmission over long lines, and in connection with power transmission over short lines where the power per circuit is very high. Of course, it is in just these cases that stability is of the greatest importance.

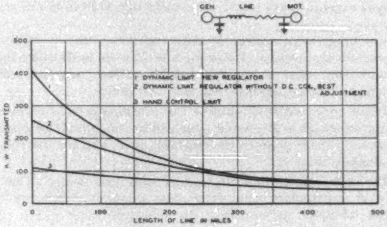

Fig. 3

Another instance is that of emergency conditions of operation. Thus, suppose a short circuit occurs and a line is dropped. In such a case it may be of great advantage to transmit a maximum of power over a weak tie line. In this case ability to operate in the zone of artificial stability should be of value.

A further consideration of very great importance is, how the regulator acts, during and after short circuits and sudden load changes. Thus, it might be supposed that the ability of the regulator to operate above the steady-state limit would disappear when short circuits and other disturbances are encountered. However, tests show that this is not the case. In general, the regulator is found to have two effects under transient conditions of operation, one an increase in the amount of power that can be carried with hand regulation, another a reduction in the tendency of machines to hunt. The amount of gain depends upon the severity of the short circuit or other disturbance. If the disturbance is slight, the gain is almost as great as that obtaining under steady conditions of operation. As the other extreme, a test in which 140 per cent resistance load is suddenly thrown onto two machines connected directly together, for a period of 0.6 sec., shows that the 230 per cent of the static limit can be carried with stability.

A test result is also available in an even more severe case. This case corresponds to a very severe short circuit on one of two parallel 250-mile lines. With the short circuit cleared at both ends in 0.6 sec., it was found that, with the new regulator, 108 per cent of the static limit of one line could be carried with stability.

---

*Same as described in paper except right-hand a-c. coil replaced by a torque motor.

Thus, the new regulator effects an improvement in stability, both under steady and transient conditions. As mentioned above, the gains under transient conditions are greater when the severity of the short circuit is less; if the short circuit is out in the middle of the line, it may be only half as severe, and consequently greater gains in stability due to the regulator are possible.

One other point of interest which may well be mentioned here is the fact that in general a somewhat different adjustment is required for best operation under transient conditions from that required under dynamic conditions. As shown by Nickle and Carothers in their paper, in the event of a short circuit or other disturbance involving a drop in machine terminal voltage the regulator acts to increase the exciter voltage in two steps, first by a sudden increase, in one vibration of the contacts, to an initial value; second, a process of continuous vibration according to which the terminal voltage is brought back to normal with a speed dependent on the degree of damping in the dashpot attached to the right hand lever. This process is illustrated in Fig. 4 herewith.

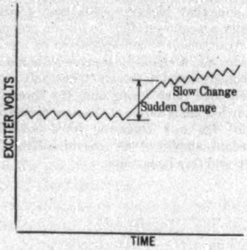

Fig. 4

The magnitude of the sudden change is freely adjustable through variation of the relative strengths of the d-c. and the a-c. elements on the left-hand lever, or, in the case of the type B regulator, by variation of the d-c. element and the stiffness of the spring in the spring dashpot.

From an analytical point of view, weakening the strength of the d-c. element relative to that of the a-c. element or the degree of elastance of the spring dashpot, corresponds to an increase in the negative resistance which the regulator inserts in the machine field. For best results under transient conditions the data at present available indicate that a low ratio of strengths of the d-c. and a-c. elements is desirable, thus corresponding to more than enough negative resistance in the machine field to compensate for its inherent positive resistance. (In general, the attainment of best all-around operation requires an adjustment involving some reduction in dynamic stability.) The exact adjustment to be employed in any particular case is variable depending on the severity and probable duration of the disturbances anticipated. The flexibility of the regulator by which it can be readily adjusted to meet any operating condition, is one of its most desirable characteristics.

**C. A. Nickle:** The discussions just presented seem to indicate that there is no serious disagreement with the main points brought out in this paper. With regard to the rheostatic type of regulator, its ability to regulate voltage under conditions of dynamic stability has been determined by test and we find that it does not seem suitable for this particular condition of operation. However, it is unquestionably satisfactory for operation below the static power limit and can satisfactorily take care of short circuits under this condition. It has been stated in the paper that this type of regulator has certain advantages not possessed by other types.

Mr. Powel has expressed the opinion that for transient conditions the only requirement of a regulator is that it close its contacts and keep them closed until the voltage is restored to approximately normal value. However, we do not believe that this is the only requirement for achieving the greatest stability under transient conditions. Sudden shocks, such as are imposed on a system by short circuits, necessarily result in system oscillations, and a regulator must be able to damp out such oscillations effectively. Otherwise, the system may break from synchronism, even after the exciting disturbance is over. The fact that a regulator closes its contacts promptly and keeps them closed until the voltage is approximately restored to normal, does not necessarily imply that the regulator has the proper antihunting characteristics.

**R. E. Doherty:** The most significant point about the discussion is that there appear to be no essential points of disagreement with what the authors consider to be the main contribution of the papers.

The foremost fact is that regulating means for increasing the maximum power of synchronous machines under conditions of dynamic stability have been much improved. Very substantial increases in maximum power above the steady-state limit, obtained by the use of the improved regulator, are given in the present papers. I do not find that anyone has questioned this fact.

To obtain such increases is an objective which has been actively sought during the last 4 or 5 years by engineers interested in power transmission. Credit is due to C. L. Fortescue for having apparently foreseen more clearly than any one else the possibility of attaining the objective by an improved regulator, and for predicting its development. Referring to tests which had demonstrated to him the *possibility* of operating in synchronism above the steady-state power limit by the use of an automatic voltage regulator (which I understand to be the a-c. coil type referred to by his associates in the present discussion), he made the following prediction at the Mid-Winter Convention in 1926:

"Now I am bringing out this point not to emphasize the point of difference, but because this artificial stability has an element of hope in it. If you can do it with a regulator today, you may be able to get a regulator that will do it still better tomorrow. You will surely be able to get more power over a given line tomorrow. Maybe the automatic regulator of special design will be the answer; maybe the inherent regulator scheme will be the answer. We don't know now, but one of these days we will know."

Such an automatic regulator of special design is now an accomplished fact, and the possible gains in maximum power by its use are promising in connection with the general development of power transmission.

Another noteworthy point on which there is practical agreement is the importance of operating through system disturbances—usually referred to under the heading of transient stability. It is agreed that this must be accomplished to the greatest practicable extent, whether the system is normally operated above the static limit or not.

Our tests show that the new regulator is efficacious in increasing the transient, as well as the dynamic, stability. In other words, it increases the power which can be carried through a system disturbance, as well as that which can be carried under steady load conditions. This is illustrated by the data which Mr. Park has given.

Thus, with reference to all of the foregoing, there appears to be no question raised in the discussion as to the results accomplished by the regulator. Nor do I find any adverse comment regarding the general theory as to how those results are accomplished—*i. e.*, by the introduction of the effect of negative resistance[5] in the field circuit by the use of the regulator. Thus as to the results and the theory which explains them, there seems to be no disagreement. And the authors regard these as the main contributions in the papers.

---

[5] It is recognized that regulators using other principles of operation can also introduce negative resistance and thus increase stability limits.

There are, however, some minor details which require explanation. Thus we are criticized, and perhaps justly, for not mentioning a test reported to have been made in 1925 in which the possibility of passing the steady-state limit was noted. However, the pertinent data regarding this test are not fully given in the literature, to our knowledge, and we know of no test since then which is comparable with those reported in the present papers. As to that one test, the conclusion drawn is freely acknowledged, namely, that it is possible to pass the steady-state limit by the use of the a-c. coil type of regulator.

As to other questions, Mr. Powel refers to the tests of Fig. 3 of my paper in which about four times the static power limit was obtained, with the statement that the ideal limit is infinity. This is merely a question as to what is taken as a standard of idealness. If the limit of the intermediate line is the standard Mr. Powel's figure is correct. However, we believe that a better standard is the degree to which the regulator compensates for armature reaction. On this basis the limiting power for comparison is that corresponding to transient reactance, and that limit is reasonably approached.

The advantage of the test with no intermediate line is that it shows the extent to which the regulator increases the capacity of the machines themselves, which is the object of the regulator. It is of course not intended that the regulator should neutralize the constants of the line. Calculations show that in practise the regulator compensates for about 95 per cent of armature reaction (*i. e.*, 95 per cent of $x_d - x_d'$).

At present it does not seem possible to overcompensate for armature reaction. Looking to the future, however, the perfection of the mercury arc rectifier and allied devices gives promise of affording improved regulating means embodying most of what appear to be the ideal regulating characteristics. With such a regulator, which would not involve vibrating contacts, it may be possible to overcompensate the armature reaction without inducing hunting.

As to "quick response," Mr. Evans questions my definition and proposes a new one. I hold no brief for the one I suggested. In the interest of accurate statement, I merely said what I meant by quick response. Now we have what Mr. Evans means by it. Any definition is all right which is generally accepted, or if not accepted, then accurately understood.

At the present writing sufficient data are not available to permit an exact statement of the best method of fulfilling excitation requirements in any given case. It would appear, however, that in many cases a moderate speed of response, say of the order of 200 volts per second on 250-volt fields, and half that much on 125-volt fields, would be sufficient. At the same time there are cases where somewhat higher speeds are desirable. Where conditions justify a maximum effort to obtain transient stability, the desirable arrangement would appear to be a combination of the new regulator and a stand-by super-excitation, the function of the latter being merely to "shoot" the excitation voltage to an appropriately high value during only the short interval of ½ second or so, the balancing action of the new regulator then being resumed. Since the new regulator itself affords first-order gains in transient stability, the combination should afford additional gains and thus be justified.

# Report of the Board of Directors

## FOR THE FISCAL YEAR ENDING APRIL 30, 1928

The Board of Directors of the American Institute of Electrical Engineers presents herewith to the membership its Forty-fourth Annual Report, for the fiscal year ending April 30, 1928. A general balance sheet showing the condition of the Institute's finances on April 30, 1928, together with other detailed financial statements, is included herein. The following is a brief summary of the principal activities of the Institute during the year, more detailed information having been published from month to month in the Institute JOURNAL.

**Directors' Meetings.**—The Board of Directors held seven meetings during the year, six in New York and one at Detroit, Michigan. The Executive Committee acted upon various matters during intervals between board meetings.

Information regarding the more important activities of the Institute which have been under consideration by the Board of Directors, the committees and the various officers, is published each month in the section of the JOURNAL devoted to "Institute and Related Activities."

**President's Visits.**—President Gherardi has attended three national and three regional conventions of the Institute during the past year and in addition has visited many of the Sections.

The following is a list of places visited: Detroit, Mich. (Summer Convention); Del Monte, Calif. (Pacific Coast Convention); New York, N. Y. (Winter Convention); Chicago, Ill. (Regional); St. Louis, Mo. (Regional); Baltimore, Md. (Regional); Regina, Can. (Saskatchewan Section); Vancouver, B. C.; Seattle, Wash.; Portland, Ore.; San Francisco, Calif.; Los Angeles, Calif.; Salt Lake City, Utah; Denver, Colo.; St. Louis, Mo.; Pittsburgh, Pa.; Ithaca, N. Y.; the president is scheduled to visit other Sections during May and the Annual Summer Convention in June.

**Meetings.**—Three national conventions of the Institute were held during the year, namely, the Summer, Pacific Coast, and Winter. The Annual Business Meeting was held in May. Regional meetings under the auspices of the Geographical Districts were held in Pittsfield, Mass., District No. 1; Chicago, Ill., District No. 5; St. Louis, Mo., District No. 7; Baltimore, Md., District No. 2.

**Annual Meeting.**—The Annual Business Meeting was held at Institute headquarters, New York, on May 20, 1927. The Annual Report of the Board of Directors for the fiscal year ending April 30, 1927, was presented. The Tellers Committee made its report upon the election of officers for the administrative year beginning August 1, 1927.

**Summer Convention.**—The Forty-third Annual Summer Convention was held at Detroit, Michigan, June 20-24, 1927. Six technical sessions were held, at which twenty-three papers and a symposium on television were presented. In addition, three other sessions were held, one being devoted to a lecture on "The Physical Nature of the Electric Arc" by Dr. K. T. Compton, and two to the presentation of fifteen technical committee reports. The Annual Conference of the Sections Committee was held on Monday, June 20; forty Sections were represented. The entertainment features included golf and tennis tournaments, a dinner, a boat trip, sightseeing, and special features. Numerous inspection trips were also made. About 1200 members and guests attended.

**Pacific Coast Convention.**—The Sixteenth Pacific Coast Convention was held at Del Monte, California, September 13-16, 1927. Four technical sessions and a general meeting were held, at which fifteen papers were presented and two addresses given. Attendance about 250.

**Winter Convention.**—The Sixteenth Winter Convention was held in New York, N. Y., February 13-17, 1928. At nine sessions twenty-nine technical papers were presented; a symposium on interconnection and its effect on power development (which included four papers and much discussion), a lecture, and a joint meeting with the Institution of Electrical Engineers by means of transatlantic telephony, were held. At another session the presentations of the John Fritz and Edison Medals took place. Numerous inspection trips, a smoker, and a dinner-dance were held. Attendance about 2000.

**Regional Meetings.**—Four regional meetings were held during the year:—the first in District No. 1 at Pittsfield, Mass., May 25-28, 1927, six technical sessions comprising forty papers were held, including one session devoted to the presentation of nine Student papers, attendance 550; second at Chicago, Ill., in District No. 5, November 28-30, four technical sessions were held, at which thirteen papers were presented, attendance 900; third at St. Louis, Mo., in District No. 7, March 7-9, 1928, four technical sessions were held at which fourteen papers were presented, attendance 500; fourth at Baltimore, Md., in District No. 2, April 17-20, four technical sessions were held, at which twelve papers were presented, attendance 400. Inspection trips and social events were a part of each of these meetings.

The importance of the regional type of meeting has been further demonstrated during the year. The total attendance at the four regional meetings was 2350 and the total attendance at the three national conventions was 2930. This large attendance and the increased interest in the Institute throughout the country, which has developed as a result of the meetings, indicate that they are a very important part of the Institute's activities.

The regional committees which have had charge of these meetings are to be highly commended for their work. The success of the meetings has been due to their ability to plan, organize, and conduct the meetings.

**Sections.**—During the past year a large majority of the Sections has been very active. A considerable number of meetings has been devoted to general or moderately technical subjects of unusual interest with excellent results, and interest in purely technical meetings has been well-maintained. The success of the four regional meetings held during the year (see listing under Regional Meetings) furnishes additional evidence of Section activity.

The Columbus and Worcester Sections became members of the newly organized Affiliated Technical Societies of Columbus and Affiliated Engineering Societies of Worcester, respectively. About one-half of the Sections are now definitely affiliated in some manner with other local organizations.

At the 1927 Sections Committee Conference, progress was made in the development of means of bringing about closer relations between engineers and the general public, and an increased interest in the subject has become apparent. It was recommended that a combined report on Section and Branch activities be prepared annually beginning with the fiscal year ending April 30, 1928, and a general plan for the report has been approved by the Board of Directors.

Many Sections have continued to carry on very effective co-operation with neighboring Student Branches by sponsoring Student Conventions, having student programs at regular Section meetings, or holding joint meetings of other types with Branches.

**Student Activities.**—Almost all Branches have been active in holding local meetings, and there has been an increased interest in joint meetings and conventions.

During the year, effective Conferences on Student Activities were held in eight Geographical Districts, and both Counselors and Branch Chairmen have been enthusiastic concerning the benefits derived.

Eight very successful Student Conventions were held, four sponsored by Sections, and four by District Committees on Student Activities, and a considerable number of Branches participated.

Through the Conferences, Student Conventions, Section and Branch co-operation, the activities of the Counselors, and the Branch meetings, definite advances have been made in the direction of bringing the students into closer contact with the Institute membership and better understanding of the opportunities for participation in its work.

Student activities have been reported more fully in the JOURNAL since the inauguration of the department for that purpose in January 1927. A revised edition of the "Suggested By-laws for Student Branches," approved by the Board of Directors, and a new pamphlet entitled "Student Activities" were printed.

New Branches were authorized at the University of Louisville and University of Vermont, and the Brown Engineering Society of Brown University became affiliated with the Institute under the provisions of Section 59A of the By-laws.

**Section and Branch Statistics.**—

| | For Fiscal Year Ending | | | |
|---|---|---|---|---|
| | April 30 1921 | April 30 1923 | April 30 1925 | April 30 1928 |
| SECTIONS | | | | |
| Number of Sections | 42 | 46 | 49 | 52 |
| Number of Section Meetings held | 303 | 344 | 386 | 431 |
| Total Attendance | 37,823 | 46,672 | 49,029 | 64,276 |
| BRANCHES | | | | |
| Number of Branches | 65 | 68 | 82 | 96 |
| Number of Branch meetings held | 443 | 503 | 548 | 915 |
| Total Attendance | 21,629 | 26,893 | 27,603 | 44,334 |

**Meetings and Papers Committee.**—The preparation of programs for national conventions and assistance with the programs of regional meetings constituted the principal work of the Meetings and Papers Committee during the year 1927-28. The committee members also, as part of their duty, reviewed miscellaneous papers submitted for publication and assisted the Prize Committee in preliminary selection of papers for prize awards.

The program for the Summer Convention, June 25-29, has been practically completed, and the schedule for the Pacific Coast Convention, August 28-31, has been tentatively arranged. The committee is also working on future meetings.

The total attendance at conventions and regional meetings was 5280, which is 800 above any previous year. The total number of papers presented was 159 including 15 annual reports of technical committees. Many noteworthy contributions to the literature in the various fields of electricity are contained in these papers.

One activity in connection with meetings on which considerable improvement has been made is the printing of advance copies of papers for distribution prior to the meetings. During the last year a much larger proportion of the papers has been printed in time for advance distribution. This improvement has resulted from special efforts exerted in three directions. First, the authors have been urged and persuaded to submit their papers well in advance. Second, the reviewing committees have reduced their time of holding papers while reviewing them. Third, the Editorial Department has obtained closer cooperation with the printers and engravers, thus eliminating delays. Another factor which will undoubtedly assist in this matter is the separation of future meeting dates by at least six weeks, as recently approved by the Board of Directors on the recommendation of the Committee on Coordination of Institute Activities.

**Publication Committee.**—The Publication Committee has paid special attention to the form of Institute publications, resulting in the policy in force since January 1928. The constantly increasing volume of papers presented at Institute meetings each year made some change imperative, as under the former scheme of publication the limit of expense had been reached, and the size of the JOURNAL and TRANSACTIONS had become unwieldy.

The present scheme of publication, which has been described at length in recent issues of the JOURNAL, consists of advance pamphlet copies of complete papers, free to A. I. E. E. members on request; abridgments, not to exceed four pages, of all papers for the JOURNAL; complete papers with discussions in the QUARTERLY TRANSACTIONS.

Five issues of the JOURNAL have been published under the new plan and reports indicate that the abridgments make the JOURNAL a more readable paper than it formerly was for the membership in general; while the requests for complete pamphlet copies are numerous enough to show that this method of providing for the specialists is functioning satisfactorily.

The first number of the QUARTERLY TRANSACTIONS was published early in February and contained the papers for the last quarter of 1927. The second quarterly will be ready for distribution during May and will contain the papers and discussions of the 1928 Winter Convention, which, it should be noted, are thus made available for reference more than a year earlier than was possible with the annual publication plan.

The last volume of Annual TRANSACTIONS, No. XLVI, is completed and will be distributed in May. It includes the papers and discussion for 1927 from January to September and contains 1178 pages.

**Law Committee.**—During the year this committee has considered various proposed amendments to the Constitution of the Institute, the most important of these being for the purpose of authorizing a change in the date of the Annual Meeting from May to the Annual Summer Convention. This change was approved by the Board of Directors and was authorized at a Special Meeting of the Institute held in Chicago in November, 1927. The various amendments as finally approved by the Law Committee and the counsel of the Institute were submitted to the membership with a letter ballot under date of April 2, 1928.

**Coordination Committee.**—The Committee on Coordination of Institute Activities has considered and made recommendations to the Board of Directors upon various matters coming within its jurisdiction under the By-laws.

These matters have included consideration and favorable report to the Board of Directors upon the recommendations made at the conference of officers and Section delegates at the Summer Convention held in Detroit, in June 1927; the overlapping of committee work; the formulation and recommendation to the Directors of a policy regarding the coordination of future national and regional meetings; and the preparation and recommendation, after requesting and receiving the suggestions of District and Section officers, of a schedule of dates and locations of meetings up to the close of 1929. The latter recommendations are fully covered in a report made to the Board of Directors under date of April 3, 1928 and approved by the Board on April 6, as published in full in the May issue of the Institute JOURNAL.

**Standards.**—The Standards Committee has continued actively the revision of existing standards and the preparation of new standards. By new standards are meant standards for types of apparatus and equipment not covered in the 1922 complete edition of Institute Standards. Twenty-six separate sections have been approved by the Board as Institute Standards. Three sections are still in so-called report form, that is, they are available for comment and criticism by the membership of the Institute before final action by the Standards Committee and recommendation to the Board. Eight of the Standards have been approved as American Standard by the American Engineering Standards Committee, but all of the Standards, except those under actual revision, have been submitted for such approval.

At the request of the Board, the Standards Committee has made recommendations for representatives of the Institute on Sectional Committees. The Institute is sole sponsor for six projects, joint sponsor for 15, and has representation on 29 other Sectional Committees under A. E. S. C. procedure. The Standards Committee receives reports from these representatives and makes recommendations to the Board based on such reports.

Spanish translations of eight standards were published by the Bureau of Foreign and Domestic Commerce, Department of Commerce, Washington, D. C., during the year. A folder in English and Spanish, listing all the standards available in the Spanish language, was prepared and widely circulated in the Spanish-speaking countries of South and Central America. Arrangements are also being made with the Bureau of Foreign and Domestic Commerce to make revisions in the Spanish text, when standards are revised.

The committee has continued very close cooperation with the United States National Committee of the

International Electrotechnical Commission. Of the 22 delegates to the Bellagio, Italy, meeting of the Commission (Sept. 1927), 18 are members of the Institute. There has been the closest cooperation between groups of advisers, U. S. N. C., I. E. C., Sectional Committees, Technical Committees, and the Standards Committee.

Several important new projects have been initiated. The formation of a Sectional Committee on definitions in the electrical field, under the sponsorship of the Institute, has been recommended. It is very desirable that there be unification and coordination of definitions in the electrical art and industry. An important and far-reaching resolution, prepared by the Instruments and Measurements Committee, on the relation of the international electrical units to the fundamental absolute units was considered and its adoption recommended to the Board.

**American Engineering Standards Committee.**—Aside from the routine matters on which the Institute delegates to American Engineering Standards Committee have been required to vote, covering such matters as the approval of standards, the delegation has attempted faithfully to serve the larger interests of American Engineering Standards Committee consistently with the policies of the Institute as laid down by the Board of Directors in the reviewing of the status of American Engineering Standards Committee and its readjustment to a changing national emphasis in the matter of standards.

The delegation has felt a primary responsibility in making clear to the other members that the American Institute of Electrical Engineers regards itself as being if not the principal at least one of the more significant influences in the inception of the work of formulating American Electrical Standards and procuring their recognition. It is believed that much has been accomplished in making clear that the American Institute of Electrical Engineers is in sympathy with the purposes and ideals of American Engineering Standards Committee. To this end the delegation has attempted to interpret the Institute to American Engineering Standards Committee and conversely to keep the Board of Directors advised of developments in American Engineering Standards Committee.

The latter organization has during the year, with the strong support of the Institute, entirely revised its methods of procedure in a manner which already has clarified and expedited the process of giving recognition to American standards and is at the present time actively concerned in the matter of a general re-constitution which shall bring the processes of standardization more nearly into coincidence with a changing condition which arises from the more general industrial recognition of the necessity for universally accepted national standards. The Institute representatives are, at the present time, taking an active part in the determination of the lines along which such re-constitution should proceed and it is believed will do so without any conflict with the fundamental purposes of the American Institute of Electrical Engineers.

**U. S. National Committee of I. E. C.**—The work of the United States National Committee of the International Electrotechnical Commission for the past year was very largely centered in preparation for and participation in the Plenary Meeting of the commission which was held in Italy, September 1927. Because of the character of its organization and the large amount of very effective work which was done by the various groups of advisors cooperating with all branches of the industry, delegates of the U. S. National Committee went to the meeting in Bellagio well prepared to put forward the views of the industry in this country in all the various matters with which the commission is concerning itself.

The meetings at Bellagio covered the period from September 3 to 11, during which time the Advisory Committees convened and very substantial progress was made in the work of the commission. This work does not lend itself readily to description in a summarized way largely because it is in different states of completion.

On the occasion of a formal dinner the American delegates presented to the Italian National Committee a bust of Benjamin Franklin on behalf of all of the eighteen visiting nationalities. The presentation was received with words of warmest appreciation.

Following the meetings in Bellagio came a tour offered by the Railway Administration of Italy, and a Plenary Meeting in Rome.

The work of the committee has been actively resumed since the Bellagio Meeting and it is the expectation of the U. S. National Committee that by the time of the next Plenary Meeting of the commission, to be held in the Scandanavian countries in 1930, a large amount of material will be ready for final consideration.

**U. S. National Committee of the International Commission on Illumination.**—The International Commission on Illumination had been scheduled to hold a Plenary Meeting in the United States in the year 1927 but for various reasons it seemed best that this Plenary Meeting should be put off for a year and a series of committee meetings should be held in Europe. Technical Committees of the Commission as well as the Executive Committee were accordingly convened at Bellagio, Lake Como, on the 31st of August and meetings were held on that day and on the 1st and 2nd of September, 1927. At these meetings the U. S. National Committee was represented by the seven delegates.

Apart from the technical matters considered there was brought up the consideration of recommendations of the U. S. National Committee with respect to the scope of the work of the commission. As a result the scope of the commission's work was considerably enlarged so that at the present time there are some fifteen subjects being considered. The Secretariats for these subjects are distributed amongst the various

National Committees, thus distributing the work and throwing an undue burden on none.

The Secretariats assigned to the United States are as follows: Headlights; Factory and School Lighting.

The Executive Committee of the Commission voted to hold the next Plenary Meeting in America in September, 1928, and the U. S. National Committee has been engaged in preparations for this meeting. It seemed to the committee that it would be fitting to request the Illuminating Engineering Society to make the necessary arrangements for this meeting. Such a request was made and accepted and the preparations for the meeting have been coming on actively.

In view of the scope of the meeting, which exceeds somewhat that of previous I. C. I. meetings because of the desire to bring in representatives of nationalities not now represented on the I. C. I., the entire meeting has been designated as an International Illumination Congress.

**Committee on Safety Codes.**—Probably the most important action taken by the committee has been the approval of the set of Standard Rules for the application of the Prone Pressure Method of Resuscitation, which was prepared for universal adoption in this country under the auspices of the United States Public Health Service, with many other organizations cooperating.

The committee also further gave its approval to the Manual of Standard Practice as prepared and approved by the American Gas Association and National Electric Light Association, which includes the rules named above.

The committee is continuing its work in endeavoring to get proper safety activities developed in the Sections and Branches. This work includes the appointment of suitable liaison officers from the National Safety Council; arrangements for cooperation with other bodies in local, community safety meetings.

The work of the Branches naturally is confined largely to suitable activities in the Branches themselves. It is the intent to direct these activities so that the graduating classes will be more fully aware of their responsibilities for accident prevention, and more fully trained in the use of tried safety methods than has been often the case in the past.

Finally, the committee has taken action recommending to the Board of Directors that the Institute offer its support to the National Safety Council in carrying through the Annual Safety Congress for 1928, which is to be held in New York City next October.

**Technical Committees.**—Reports of Technical Committees embracing an outline of the year's work and a summary of progress in the industry will be presented at the Annual Summer Convention and printed in the TRANSACTIONS.

**Membership.**—The following table gives the number of members added to the roll during the year and the number whose affiliations have terminated through resignation, death, or delinquency in dues. The membership total as of May 1, 1928, is 18,265. The slight decrease in total membership, as shown, is due to special causes of a temporary nature, which operated during the year.

| | Honorary | Fellow | Member | Associate | Total |
|---|---|---|---|---|---|
| Membership on April 30, 1927 | 4 | 644 | 2,931 | 14,770 | 18,349 |
| Additions: | | | | | |
| Transferred | | 26 | 255 | | |
| New Members Qualified | | 1 | 77 | 1,503 | |
| Reinstated | | 1 | 12 | 81 | |
| Total | 4 | 672 | 3,275 | 16,354 | 20,305 |
| Deductions: | | | | | |
| Died | | 8 | 20 | 48 | |
| Resigned | | 4 | 26 | 440 | |
| Transferred | | | 17 | 204 | |
| Dropped | | 1 | 48 | 1,164 | |
| Membership April 30, 1928 | 4 | 659 | 3,164 | 14,438 | 18,265 |

**Deaths.**—The following deaths have occurred during the year.

*Fellows:* James R. Craighead, Elmer E. F. Creighton, William C. L. Eglin, Alexander C. Humphreys, James Kynoch, Paul Spencer, Charles Vernier, James J. Wood.

*Members:* Frederick L. Baer, James E. Barker, Louis C. Brooks, Aubrey L. Broomall, Harry L. Brown, Blanchard C. Edgar, Carlo Ferrari, Frank E. Field, James M. Graves, George Ross Green, Charles T. Guildford, Harry E. Hayes, George L. Hedges, Augustus T. Holbrook, Robert M. Lloyd, Allen H. Moore, Michael C. Polivanoff, Ernest E. Schmid, Irving W. Smith, Hugh T. Wreakes,

*Associates:* Jean B. Balcomb, William K. Benz, Ole S. Beagstad, Abel L. Brownrigg, Charles F. Brush, Jr., George A. Buchanan, William C. Chappell, Henry H. Curtis, R. T. Davis, Charles S. Dawson, Charles P. Drake, George Eisenhauer, Charles H. Fisher, Sydney Fisher, Maurice C. Fitzgerald, George H. Gettess, William F. M. Goss, Baxter R. Grier, Edmund M. Hallowell, James W. Harris, Alexander W. Hearne, Harry G. Hopkins, Roy D. Huxley, Frank E. Idell, Johannes Johansen, Senter M. Jones, Paul T. Kamerer, Keijiro Kishi, Arthur R. Leavitt, Basil W. Lee, Archie L. Lewis, Gordon E. McLean, Robert Miller, Otis Sherman Newton, Frederick E. Norman, Ralph M. Obergfell, John L. Phillips, William E. Poole, Fred B. Seem, Frederick G. Simpson, Walter Stumpf, Soichi Takeda, Frank F. Thompson, Howard F. Thurber, Beverley B. Tucker, Thomas A. Wilkinson, Harold P. Williamson, Byron M. Wood.

**Board of Examiners.**—The Examiners have had before them during the past year the question of the comparative number of members of the Institute in the three grades of Associate, Member, and Fellow, and whether the present number in those grades represented a true cross-section of the electrical field with regard to the professional accomplishments of the members and the positions held. A special committee has been authorized by the Directors to consider this entire question. The total number of cases of admission and transfer considered by the Examiners this year is indicated below:

Applications for Admission

| | | |
|---|---|---|
| Recommended for grade of Associate | 1243 | |
| Not recommended | 13 | 1256 |
| Recommended for grade of Member | 78 | |
| Not recommended for admission to this grade | 25 | 103 |
| Recommended for grade of Fellow | 2 | |
| Not recommended for admission to this grade | 1 | 3 |
| Recommended for enrolment as Students | | 1967 |

Applications for Transfer

| | | |
|---|---|---|
| Recommended for grade of Member | 280 | |
| Not recommended for transfer to this grade | 17 | 297 |
| Recommended for grade of Fellow | 21 | |
| Not recommended for transfer to this grade | 3 | 24 |
| Total number of applications considered | | 3650 |

**Institute Prizes.**—At the meeting of the Board of Directors of the Institute of June 23, 1927, recommendations of the Committee on Award of Prizes were approved establishing five National prizes of $100.00 cash and suitable certificates to be awarded yearly as follows: Three First Prizes for (a) Engineering Practise, (b) Theory and Research, (c) Public Relations and Education; and in addition a Prize for Initial Paper and Prize for Branch Paper. The following Regional prizes may also be awarded yearly in each of the ten Geographical Districts, each prize to consist of $25 and suitable certificate, as follows: First Prize, Prize for Initial Paper, Prize for Branch Paper.

The awards for the year 1927 have not as yet been made but the committee's report is expected in May. The presentations will take place at the Denver meeting.

**Scholarships.**—The governing bodies of Columbia University have placed at the disposal of the Institute each year a scholarship in electrical engineering for each class. The awards are made annually by an Institute committee. The scholarships pay $350 toward annual tuition with provision for reappointment. An award for the academic year 1927-28 was made to Walter L. Lawrence.

Complete details governing prizes and scholarships may be obtained by applying to the National Secretary of the Institute.

**Edison Medal.**—The Edison Medal, founded by associates and friends of Thomas A. Edison, is awarded annually by a committee consisting of twenty-four members of the Institute "for meritorious achievement in electrical science, electrical engineering, or the electrical arts." The medal for 1927 was awarded to William D. Coolidge, "for his contributions to the incandescent electric lighting and the X-ray arts." The presentation took place at the Winter Convention of the Institute, February 15, 1928.

**John Fritz Medal.**—The John Fritz Medal Board of Award, which is composed of representatives of the national societies of Civil, Mining, Mechanical, and Electrical Engineers, awarded the twenty-fourth medal to John J. Carty, of New York, "for achievements in telephone engineering." The medal was presented at New York at the Winter Convention of the Institute, February 15, 1928.

**Lamme Gold Medal.**—A bequest was made by the late B. G. Lamme, to cover the cost of an annual award by the Institute of a gold medal, to a member who has shown meritorious achievement in the development of electrical apparatus. The conditions governing the award of the Lamme Gold Medal are now being prepared by a special committee.

**Commission of Washington Award.**—The Washington Award for 1928 was made to Dr. Michael I. Pupin "for devotion to scientific research leading to his inventions which have materially aided the development of long distance telephony and radio-broadcasting."

The award is made annually "to an engineer whose work in some special instance, or whose services in general have been noteworthy for their merit in promoting the public good," by a committee composed of nine representatives of the Western Society of Engineers and two each from the A. S. C. E., the A. I. M. E., the A. S. M. E., and the A. I. E. E.

**Employment Service.**—The employment service which the Institute has maintained for many years is conducted as a cooperative bureau in conjunction with a similar service maintained by the National Societies of Civil, Mining, and Mechanical Engineers under the title, "Engineering Societies Employment Service." In addition to the main office in the Engineering Societies Building, New York, offices have been opened in Chicago in cooperation with the Western Society of Engineers and in San Francisco under similar arrangements with the California Section, American Chemical Society, and Engineers Club of San Francisco. Arrangements have been completed to open a branch office in Denver, Colorado, in cooperation with the Colorado Engineering Society. It is hoped to continue this development from year to year as conditions warrant. The service is supported by the joint contributions of the societies and their individual members who are benefited. As in the past it consists principally in acting as a medium for bringing together the employer and the employee. In addition to the publication of the "Employment Service Bulletin" in the monthly JOURNALS, weekly subscription bulletins are issued for those seeking positions.

**American Engineering Council.**—American Engineering Council, with which the Institute is affiliated, is completing its eighth year as representative of its constituents, at conferences, conventions, on important committees of other organizations, and at Congressional hearings. It now has a membership of 25 national, state, and local engineering societies totalling an individual membership of something over 43,000 professional engineers.

During the past year it has extended aid of a valuable character to over 200 societies and individuals. Council is becoming well known as an authoritative source of information and reference.

Council, however, does not confine itself to such activities but pursues many other projects. It has representatives on such government committees as the Advisory Council to the Board of Surveys and Maps, the Planning Committee of the Division of Simplified Practice, the Committee appointed to draft a Uniform State Mechanics Lien Act, and the several executive committees of the Hoover Conference on Street and Highway Safety. It likewise has representatives on committees formed by other groups, as the U. S. Chamber of Commerce, the National Bureau of Economic Research, the World Congress of Engineers, and the celebration of the 200th anniversary of the birth of George Washington.

The legislative year has been an exceedingly busy and active one.

The Public Affairs Committee is completing the busiest year of its existence. Never before since the establishment of Council have so many bills been introduced into a single session of Congress which have come so directly within the purview of American Engineering Council.

Council has continued its active support of and is hopeful that most of the following measures will be passed during this session of Congress: Newton Bill, calling for an inventory of the water resources of the United States; Parker Bill, providing an equitable status for sanitary engineering and sanitary engineers in the U. S. Public Health Service; Wyant Bill, which assembles the greater part of the civil engineering and construction services of the Government under one government division in the Department of the Interior; Ransdell Bill, which calls for the establishment of a national hydraulic laboratory in the U. S. Bureau of Standards; and the McNary-Woodruff and McNary-McSweeney Bills which provide for a fixed national forestry policy and for an augmented research program by the Department of Agriculture in certain matters pertaining to forestry.

The Council has continued its opposition to the Swing-Johnson Bill; to legislation seeking to grant certain patents to Garabed K. Giragossian, without jurisdiction of the Patent Office; to Government ownership and operation of certain projects, as Muscle Shoals; to any legislation which tends to nullify the Federal Power Commission's jurisdiction.

The year has seen the completion of two studies: Safety and Production; and Street Signs, Signals, and Markings. Safety and Production is now off the press and being distributed. The report on Street Sigsn, Signals, and Markings will be issued in pamphlet form within the next few months. It is expected that the recommendations of the Committee on Street Signs, Signals, and Markings will be adopted as American standard. Legislative activity is now under way which will culminate in the adoption, almost in toto, of the recommendations of Council's Committee as state requirements by the State Legislatures of New York and of New Jersey.

Important special committees which will function throughout the year are Flood Control, Radio Broadcasting, President's Committee on Constitution, By-Laws and Activities of American Engineering Council, Patents, Power, and Program of Research.

The Flood Control Committee has been and will continue to be active in connection with the Mississippi Valley flood problems; the Radio Broadcasting Committee is continuing to render valuable assistance to the Federal Radio Commission; the Patents and Power Committees have been active in connection with numerous pieces of legislation, both desirable and undesirable, which have been before Congress for consideration. The Program of Research Committee is undertaking to establish certain fundamental principles which shall govern future research policies of American Engineering Council.

**United Engineering Society.**—This Society performs for the national societies of Civil, Mining, Mechanical, and Electrical Engineers, certain specific acts which are governed by contracts; the primary function of the United Society being to hold in trust and to administer for these societies the Engineering Societies Building, in which the headquarters of the national societies are located.

Extracts from the annual financial report of the United Engineering Society were published in the March 1928 JOURNAL.

**Engineering Societies Library.**—The library of the Institute is combined with the libraries of the national societies of Civil, Mining, and Mechanical Engineers, administered as the "Engineering Societies Library" under the direction of the Library Board of the United Engineering Society; this board is composed of representatives of each of the four societies referred to above.

In order to place the facilities of the library at the disposal of persons residing at a distance from New York, a Library Service Bureau has been established, and a staff of expert searchers and translators is employed to cover almost any engineering topic, in the following manner: abstracting, translating, bibliographing, statistical searches and reports, searches for patent purposes, copying, preparing reference cards, etc. A lending department is also maintained.

A copy of the annual report of the Engineering Societies Library covering the calendar year 1927, may be obtained by applying to Institute headquarters.

**Engineering Foundation.**—Engineering Foundation is a trust fund established in 1914 by Ambrose Swasey, of Cleveland, Ohio, by gifts to United Engineering Society as a nucleus of a large endowment "for the furtherance of research in science and in engineering, or for the advancement in any other manner of the profession of engineering and the good of mankind." The fund has been generously increased through the gifts of Edward D. Adams and others, and also through bequest under the will of the late Henry R. Towne. It is administered by the Engineering Foundation Board upon which the Institute and other national engineering societies are represented. The Board is a Department of United Engineering Society.

The Foundation has made appropriations for various research projects and has cooperated in others.

The annual report of the Foundation is available in printed form.

**Representatives.**—The Institute has continued its representation upon various national committees and other local and national bodies with which it has been affiliated in past years, and has accepted sponsorship and appointed representatives upon a number of new Sectional Committees of American Engineering Standards Committee. A complete list of representatives is published frequently in the JOURNAL.

**Finance Committee.**—During the year the committee has held monthly meetings, has passed upon the expenditures of the Institute for various purposes, and otherwise performed the duties prescribed for it in the Constitution and By-laws.

Haskins and Sells, certified public accountants, have audited the books, and their report follows:

---

Respectfully submitted for the Board of Directors

F. L. HUTCHINSON,

*National Secretary.*

New York, May 18, 1928

May 17, 1928.

American Institute of Electrical Engineers,
33 West 39th Street,
New York.

Dear Sirs:

We have made a general audit of your accounts for the year ended April 30, 1928, and submit the following exhibits and schedule:

Exhibit

A—Balance Sheet, April 30, 1928.
Schedule 1—Reserve Capital Fund—Securities.

B—Summary of Income and Profit and Loss for the Year Ended April 30, 1928.

WE HEREBY CERTIFY that in our opinion Exhibits A and B, respectively, correctly set forth the financial condition of the Institute at April 30, 1928, and the results of its operations for the year ended that date.

Yours truly,
HASKINS & SELLS

**Exhibit A.**

## Balance Sheet, April 30, 1928

### ASSETS

| | | | |
|---|---|---|---|
| **Real Estate:** | | | |
| One-fourth interest in United Engineering Society's Land, Building, and Building Equipment, 25 to 33 West 39th Street (Depreciation carried on books of United Engineering Society) | | | $493,352.60 |
| **Equipment:** | | | |
| Library—Volumes and Fixtures | | $ 41,298.96 | |
| Works of Art, Paintings, etc | | 3,001.35 | |
| Office Furniture and Fixtures | $27,037.87 | | |
| Less Reserve for Depreciation (including $5,884.29 funded) | 10,316.68 | 16,721.19 | |
| Total Equipment | | | 61,021.50 |
| **Working Assets:** | | | |
| "Transactions," etc | | $ 4,490.75 | |
| Paper and Cover Paper | | 5,245.94 | |
| Badges | | 2,181.12 | |
| Total Working Assets | | | 11,917.81 |
| **Current Assets:** | | | |
| Cash | | $ 12,551.96 | |
| Accounts Receivable: | | | |
| Members—For Dues | | 23,735.68 | |
| Advertisers | | 1,147.00 | |
| Miscellaneous | | 5,457.33 | |
| Accrued Interest on Investments | | 1,994.53 | |
| Total Current Assets | | | 44,886.50 |
| **Funds:** | | | |
| Reserve Capital Fund: | | | |
| Securities—Schedule 1 | | $143,711.88 | |
| Life Membership Fund: | | | |
| Cash | $ 6,438.56 | | |
| Chicago, Burlington & Quincy Railroad Company 4% Bonds, 1958, Registered, Par Value $5,000.00. | 4,868.75 | | |
| Accrued Interest | 33.33 | 11,340.64 | |
| International Electrical Congress of St. Louis—Library Fund: | | | |
| Cash | $ 990.74 | | |
| New York City 4½% Corporate Stock, 1957, Par Value $2,000.00 | 2,204.05 | | |
| New York Telephone Company 4½% Bond, 1939, Registered, Par Value $1,000.00 | 878.75 | | |
| Accrued Interest | 67.50 | 4,141.04 | |
| Mailloux Fund: | | | |
| Cash | $ 2.50 | | |
| New York Telephone Company 4½% Bond, 1939, Registered, Par Value, $1,000.00 | 1,000.00 | | |
| Accrued Interest | 22.50 | 1,025.00 | |
| Lamme Medal Fund: | | | |
| Cash | $ 894.83 | | |
| Baltimore and Ohio Railroad Company 6% Refunding and General Mortgage Series "C" Bond, 1995, Par Value $4,000.00 | 4,330.00 | | |
| Accrued Interest | 100.00 | 5,324.83 | |
| Depreciation of Furniture and Fixtures Fund: | | | |
| Cash | $ 871.79 | | |
| Cleveland Union Terminals Company 5% Sinking Fund Series "B" Gold Bonds, 1973, Registered, Par Value $5,000.00 | 5,012.50 | 5,884.29 | |
| Total Funds | | | 171,427.68 |
| Total | | | $782,606.09 |

### LIABILITIES

| | | |
|---|---|---|
| **Current Liabilities:** | | |
| Accounts Payable | $ 14,182.09 | |
| Dues Received in Advance | 2,772.07 | |
| Entrance Fees and Dues Advanced by Applicants for Membership | 556.85 | |
| Subscriptions for "Transactions" Received in Advance | 79.00 | |
| Total Current Liabilities | | $ 17,590.01 |
| **Fund Reserves (Not Including Depreciation Reserves):** | | |
| Reserve Capital Fund | $143,711.88 | |
| Life Membership Fund | 11,340.64 | |
| International Electrical Congress of St. Louis—Library Fund | 4,141.04 | |
| Mailloux Fund | 1,025.00 | |
| Lamme Medal Fund | 5,324.83 | |
| Total Fund Reserves (Not Including Depreciation Reserves) | | 165,543.39 |
| **Surplus**, Per Exhibit "B" | | $599,472.69 |
| Total | | $782,606.09 |

## AMERICAN INSTITUTE OF ELECTRICAL ENGINEERS

### SUMMARY OF INCOME AND PROFIT AND LOSS FOR THE YEAR ENDED APRIL 30, 1928

**Exhibit B.**

| | | | |
|---|---|---|---|
| **Income:** | | | |
| Dues | | *$227,666.66 | |
| Students' Fees | | 10,917.00 | |
| Entrance Fees | | 15,525.00 | |
| Transfer Fees | | 1,460.00 | |
| Advertising | | 82,978.19 | |
| Journal Subscriptions | | 10,164.38 | |
| "Transactions" Subscriptions | | 19,503.19 | |
| Miscellaneous Sales | | 10,126.09 | |
| Badges Sold | $ 4,290.65 | | |
| Less Cost | 3,505.08 | 785.57 | |
| Interest on Securities in Reserve Fund | | 6,874.20 | |
| Interest on Bank Balances | | 1,220.69 | |
| Total | | | $387,220.97 |
| **Expenses:** | | | |
| Publications: | | | |
| Journal | $103,497.42 | | |
| "Transactions" | 31,250.50 | | |
| Year Book | 7,626.27 | | |
| Miscellaneous | 3,778.94 | $146,153.13 | |
| Institute Meetings | | 25,953.90 | |

| Code Committee, | | 60.00 | |
| Technical Committees | | 192.45 | |
| Edison Medal | | 308.10 | |
| Law Committee (Revision of Constitution) | | 1,019.39 | |
| Geographical Districts Expense: | | | |
| Traveling expense: | | | |
| Executive Committee | $ 1,523.69 | | |
| Vice-Presidents | 973.99 | | |
| Speaker's Bureau | 64.26 | | |
| Best Paper Prize | 100.00 | | |
| First Paper Prize | 75.00 | 2,736.94 | |
| Branch Activities: | | | |
| Meetings | $ 537.26 | | |
| Traveling Expense—Counsellors. | 5,286.33 | | |
| Salaries and Miscellaneous | 2,435.65 | 8,259.24 | |
| Forward | | $293,084.10 | $387,220.97 |

| | | | |
|---|---|---|---|
| **Total Income—Forward** | | | $387,220.97 |
| **Expenses—(Forward)** | | $293,084.10 | |
| American Engineering Standards Committee | | 1,500.00 | |
| International Electrotechnical Commission | | 1,521.16 | |
| United States National Committee of International Commission on Illumination | | 300.00 | |
| Louvain Memorial | | 929.27 | |
| President's Special Appropriation | | 357.24 | |
| Board of Directors—Traveling Expenses | | 3,668.46 | |
| National Nominating Committee, Traveling Expenses | | 979.03 | |
| Institute Representatives—Traveling Expenses | | 178.27 | |
| Honorary Secretary | | 4,000.00 | |
| John Fritz Medal | | 417.53 | |
| Engineering Societies Library—Maintenance | | 8,729.14 | |
| United Engineering Society Assessment | | 5,711.04 | |
| American Engineering Council | | 17,725.00 | |
| Engineering Societies Employment Service | | 1,635.00 | |
| International Annual Tables | | 100.00 | |
| Institute Prizes | | 400.00 | |
| Total | | | 341,235.24 |
| **Net Income** | | | $ 45,985.73 |
| **Profit and Loss Credits:** | | | |
| Adjustment of Inventories: | | | |
| "Transactions" | $ | 669.25 | |
| Library Volumes and Fixtures | | 691.12 | 1,360.37 |
| **Gross Surplus for the Year** | | | $ 47,346.10 |
| **Profit and Loss Charges:** | | | |
| Uncollectible Dues and Members' Charges Written Off | | $ 12,110.35 | |
| Furniture, Fittings and Equipment Scrapped or Sold—Net | | 117.23 | |
| Provision for Depreciation of Furniture and Fixtures | | 1,343.66 | |
| Total | | | 13,571.24 |
| **Surplus for the Year** | | | $ 33,774.86 |
| **Surplus, May 1, 1927** | | $602,756.01 | |
| †Less Transferred to Capital Fund Reserve in Accordance with Resolution of the Board of Directors | | 37,058.18 | 565,697.83 |
| **Surplus, April 30, 1928** | | | $599,472.69 |

*Includes $103,724.00 allocated to subscriptions for the JOURNAL and TRANSACTIONS.

†Includes authorized investments for appropriation year beginning October 1, 1926 and part of authorized investments for ensuing year.

# Application of Wound Type Current Transformers Installed in High-Voltage Oil Circuit Breaker Tanks

BY J. C. REA[1]

Associate, A. I. E. E.

*Synopsis.—Wound type current transformers installed in the tanks of high-voltage oil circuit breakers have been in operation for many years. The experience gained during this period has resulted in fairly clear definitions as to the types of installations to which they are best suited, and to designs of transformers which are highly reliable. The purpose of this paper is to present a brief history of some of the developments leading up to the present application of wound type current transformers in circuit breakers and to indicate some of the conditions under which they offer special advantages.*

* * * * *

IN the early stages of the electric power industry the oil circuit breaker made its appearance as a solution of the problem of interrupting circuits under load and it was not surprising that efforts were soon made to develop automatic mechanisms which would cause the circuit breaker to open itself on over-current. Some of the earliest forms of devices for performing this duty took the form of solenoid coils connected in series with the circuit controlled by the circuit breaker. These coils acted as electromagnets in a mechanism which was designed to release the operating mechanism of a circuit breaker when a predetermined amount of current flowed through the series coil. The operating mechanism would then throw the circuit breaker to the open position.

A device of this nature was manufactured in 1910 for installation on indoor circuit breakers where it was unnecessary to protect it from the weather. The series coil was mounted on the top of the oil circuit breaker bushing and the motion of the electromagnet was transmitted to the control mechanism through a glass tube which served to insulate the electromagnet from the control mechanism. A further step in the development of this device was to provide for its protection from the weather when used in outdoor oil circuit breakers. This was accomplished by moving the series trip coil to the inner end of the entrance bushing where it operated submerged in oil.

The series trip coil was mounted on the lower end of the bushing. An insulating plate was bolted between the lower end of the bushing conductor and the support for the breaker contact. The series trip coil was connected across this insulating member so that the current flowing through the breaker passed through the trip coil.

The motion was transmitted from the electromagnet to the control mechanism by means of a vertical insulating rod which connected to a lever on a shaft running between the three phases of the circuit breaker. This shaft when rotated released the opening mechanism. Devices of this nature all had the serious defect of requiring very delicate adjustments because the amount of energy available was very small. They also lacked a satisfactory means for varying the time delay.

These defects were readily overcome by the use of current transformers connected to suitable relays. The desired time delay characteristics were obtainable with this combination and additional features such as differential protection, reverse power control, etc., could also be obtained. The current transformers, however, in many cases added a very considerable item of expense to the installation, particularly in the higher voltages.

The use of the entrance bushing on the oil circuit breaker offered a means to provide insulation for the primary circuit of the current transformer, eliminating one of the heaviest items of expense in connection with its use. This means was used either by applying a bushing type transformer in which the primary winding was formed by the conductor passing through the bushing, or a transformer with a primary coil wound on the core and mounted in the oil circuit breaker tank.

In the case of the bushing type transformer no change was required in the conducting parts of the oil circuit breaker in order to pass the primary current through the current transformer.

In applying the wound-type current transformer inside the circuit breaker tank it was necessary to insert the primary coil in series with the conducting parts in the breaker.

## EARLY FORMS OF TRANSFORMERS

In an early form of transformer of this type the primary coil was provided with a bracket which formed one of the leads and was located at the lower end of the bushing. The transformer was arranged with two equal primary windings which could be connected by means of links into either a series or parallel connection so as to obtain two ratios. The bracket lead was fastened to one of the contact members in the oil circuit breaker and formed a partial support for the transformer. The other end of the primary winding

*Presented at the Northeastern District No. 1 Meeting of the A. I. E. E., New Haven, Conn., May 9-12, 1928.*

was connected to the conductor at the lower end of the entrance bushing. An insulating plate, bolted between the lower end of the bushing conductor and the support for the breaker contact, caused the current to flow through the primary coil.

As this transformer was designed for use with circuit breakers having dimensions already established, it was necessary to make the primary coil as small as possible and to aid in obtaining this result the secondary coil was placed on the leg of the core opposite to that on which the primary coil was located. This construction not only permitted a small primary coil to be used but also enabled the insulation to be split into two sections. The core was given an equal amount of insulation both from the primary and the grounded secondary coil so that the dielectric stress on the insulation at the primary coil was considerably reduced from that which would have existed if all of the insulation had been applied at one point. The secondary coil leads were brought out along a bracket connection which was built into the secondary coil and which aided in supporting the transformer by being fastened to the top cover of the oil circuit breaker. Transformers of this type were applied to oil circuit breakers ranging from 22,000 to 110,000 volts. They were used for tripping purposes and for operating indicating ammeters for which they were very satisfactory.

The principal reason for the use of these transformers rather than bushing type transformers was to take care of the tripping of high-voltage oil circuit breakers where the current at which tripping was desired was so low that satisfactory performance could not be obtained with bushing type transformers. The accuracy of ratio and phase angle of these transformers with wound primary coils was not sufficient to permit their application to metering. The placing of the primary and secondary coils on the opposite sides of the core also caused a high leakage flux which gave the transformers rather poor characteristics on heavy overloads. This interfered with their application to differential protection of transformer banks.

These weaknesses were not easily remedied because of the space limitations which were imposed on the transformer, due to its being mounted in the tank of the oil circuit breaker. The characteristics obtained and the very material saving in cost over externally mounted transformers made this type of equipment of distinct advantage for many installations.

Further development was made possible by increasing the space available inside of the tanks, permitting the physical dimensions of the transformer to be increased. Improved electrical characteristics were obtained by mounting the primary and secondary coils concentrically upon one leg of the core and increasing the number of ampere-turns and cross-section of core. The characteristics thus obtained made the transformer suitable for metering. The mechanical strength of the transformer as a unit, and also of its mounting in the oil circuit breaker, were also greatly improved by this construction.

The insulation between the primary and secondary coils presents a rather unusual problem because of the possibility of the transformer being operated, at times, in oil of reduced dielectric strength. It is also necessary to provide for a possible accumulation of carbon and other deposits which may adhere to the surface of the insulation.

A type of construction for the major insulation, which has proved highly satisfactory, consists of concentric tubes of laminated phenol compound supported on rings of the same material. Shoulders are turned on the tubes and the supporting rings are pressed against them so that the tubes cannot slip along their axis. The free circulation of the oil between the tubes is insured by perforating the supporting rings. This construction provides for a very long leakage path between the primary coil and ground.

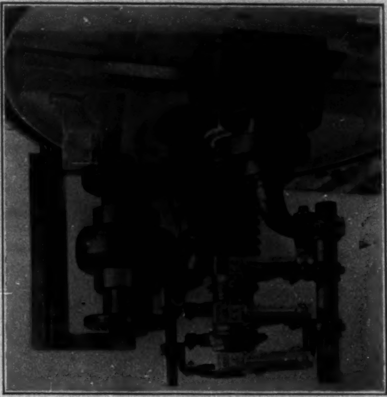

FIG. 1—73-KV. OIL CIRCUIT BREAKERS WITH MODERN WOUND TRANSFORMER

Additional leakage surface is obtained by applying a porcelain tube with a corrugated flange at each end of the Bakelite insulating tube.

## MODERN DESIGNS OF TRANSFORMERS

Figs. 1 and 2 show typical transformers of this construction. The outer coil is the primary which in the transformer illustrated is wound in two sections. Links are provided to permit the sections to be connected, either in series or parallel to obtain two different ratios. The secondary coil is wound on a tube which fits against the core, directly under, and concentric with the primary coil. The secondary leads can be seen, running out to the secondary terminal block at the top of the transformer. The symmetrical arrangement of the coils limits the mechanical forces, due to heavy primary currents, to a minimum.

The mounting of a current transformer in an oil circuit breaker tank calls for particular care because of the mechanical shocks to which the transformer is subjected during the interruption of the circuit by the oil circuit breaker. It has been found that if very substantial support is given to the core of the transformer it will withstand these shocks without sustaining any injury.

Fig. 1 shows a typical mounting of one of these transformers in a multiple-break oil circuit breaker of the rotary type. The core is rigidly held by a bracket which is secured to the cover of the oil circuit breaker. The primary coil is in turn fastened to the lower end of the entrance bushing by means of heavy copper links. The location of the transformer relative to the contacts of the breaker is such that it is at no time endangered by proximity to the arcs, which are drawn upon opening the breaker. In extreme cases, where the number of instruments to be operated exceeds the capacity of one transformer, two of these transformers can be mounted in each phase of the oil circuit breaker. In this case one transformer is applied to each of the entrance bushings.

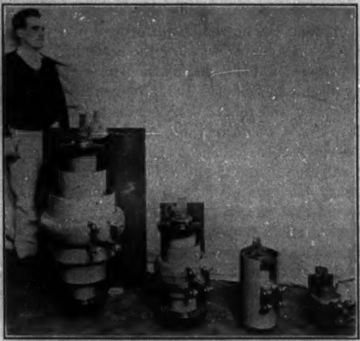

Fig. 2—Comparison of 132-Kv., 73-Kv., 37-Kv., and 25-Kv. Transformers

In some of the earlier transformers of this type trouble was experienced due to surges causing a failure of the insulation between turns in the primary coil. Various protective devices were tried. It was found that by applying very generous insulation between turns on the primary all trouble from this source was eliminated and that protective devices to shunt the surges across the primary coil were unnecessary.

A line of transformers has been developed to cover voltages from 25 kv. to 132 kv. The general construction of these transformers is fairly uniform for the entire range of voltages. Fig. 2 shows the relative size of some of these transformers. The smallest transformer shown is rated at 25 kv. The next larger transformer is a special design and is provided with a cylindrical barrier around the primary coil to permit its installation in a 37-kv. circuit breaker which has a very limited space for the transformer. The third transformer is for mounting in a 73-kv. oil circuit breaker, and the largest one is for mounting in a 132-kv. oil circuit breaker.

This type of transformer has been developed to cover the range of ratios from 5/5 up to 400/5. The primary ampere turns on the lower ratio transformers is approximately 1000, while on the higher ratios 1200 ampere-turns are used. This variation in ampere-turns is brought about by the necessity of providing for the additional insulation in the lower ratio primary coils, which have a large number of turns. The characteristics of the transformers are only slightly affected by this variation in the number of ampere-turns for the different ratios.

## Applications

The application of wound type current transformers in the tanks of oil circuit breakers is particularly advantageous in meeting two distinctly different requirements. One of these cases is where it is necessary to operate watt-hour meters for measuring small amounts of power, where the required accuracy cannot be obtained from bushing type transformers. The second use to which these transformers can be very advantageously applied is to operate tripping relays where the primary current is low and the secondary burden on the transformer is high.

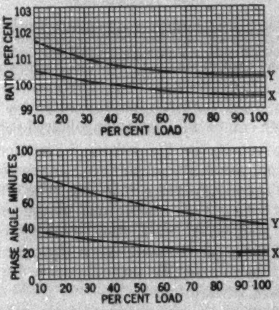

Fig. 3—Characteristics of Wound Transformer

X 2.5 Volt-amperes, 90 per cent power-factor burden
Y 15 Volt-amperes, 90 per cent power-factor burden

For the first case, Fig. 3 shows the ratio and phase-angle curves obtained with this type of wound transformers when operating with burdens of 0.1 ohm resistance 0.13 $\mu$ h. or approximately 2½ volt-amperes, 90 per cent power factor, and of 0.6 ohms resistance 0.7 μ h. or approximately 15 volt-amperes, 90 per cent power factor. These curves are characteristic for the type of transformers herein illustrated over their total range of 5/5 ratio to the upper limit of 400/5 ratio. Where extreme accuracy is needed the ratios can be adjusted by turn compensation to get zero error at any per cent of primary load desired. This is accomplished by the use of two parallel secondary windings having an unequal number of turns. By choosing a suitable combination of turns for these secondary coils, the ratio for a given primary current and burden can be adjusted to any desired value.[2]

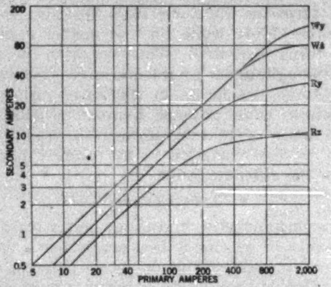

FIG. 4—COMPARISON OF 50.5 RATIO, BUSHING, AND WOUND TYPE TRANSFORMERS

| | |
|---|---|
| W Y | Wound transformer 15 volt-amperes burden |
| W Z | Wound transformer 50 volt-amperes burden |
| R Y | Bushing transformer 15 volt-amperes burden |
| R Z | Bushing transformer 50 volt-amperes burden |

For the second case, Fig. 4 shows the relation between primary and secondary amperes of a conventional 50/5 ratio (10 secondary turns) bushing type transformer and of a wound type transformer of the same ratio. A rating somewhat below that generally considered the minimum for bushing type transformers was chosen so as to magnify the differences between the two types of transformers.

The effect of the distribution of the primary and secondary windings relative to the core of bushing type transformers has been investigated by the Committee on Protective Devices. (JOURNAL of A. I. E. E., August 1927.) Their report shows that a minor error may be caused by an unsymmetrical distribution of the primary and secondary windings. In order to avoid any error from this cause the curves shown in Fig. 4 were taken from a bushing type transformer in which the secondary turns were evenly distributed around the core, and the primary was carefully centered. The curves are shown for burdens of approximately 15 volt-amperes and 50 volt-amperes.

A point that is occasionally overlooked in the application of induction type over-current relays to current transformers is the excessively high burden which they impose on the transformer when they are connected on the low current taps. A type of relay frequently used with bushing type current transformers has a nominal rating of 2-volt-amperes at the tap current. If such a relay is connected to the transformer and operated on the two ampere tap the impedance of the relay alone is approximately equivalent to a burden of 12.5-volt amperes at 5 amperes secondary current of the transformer.

The usual installation of high-voltage oil circuit breakers, requires a considerable length of wire to be run between the current transformers and the relays. Using No. 10 copper wire for the secondary leads, the volt-ampere burden added by the wire is approximately five volt-amperes for each 100 ft. of distance between the transformer and relay. The curves marked *W Y* and *R Y* in Fig. 4 would be those resulting from the use of a two-volt ampere induction type relay connected on the two ampere tap and mounted 50 ft. from the oil circuit breaker. Using a 50/5 ratio transformer it would be expected that the relay would trip the breaker at a minimum of 20 amperes primary current. However, the chart shows that while this would be true with the wound type transformer it would require a minimum of 30 amperes primary current to operate the relay from the bushing type current transformer. Approximately the same burden would be obtained with a 12-volt-ampere relay connected on the five ampere tap, or a 17-volt-ampere relay connected on the six ampere tap, when either relay is located 50 ft. from the current transformer.

The curves marked *W Z* and *R Z* are those obtained with a secondary burden of 50 volt-amperes, 50 per cent power factor. Approximately this amount of burden would be imposed by a 2-volt-ampere relay connected on the one ampere tap or a 17-volt-ampere relay connected on the 3-ampere tap, either of these being located 50 ft. away from the circuit breaker. In this case the bushing type transformer would require more than twice the primary current to operate the relay than that required by the wound type current transformer.

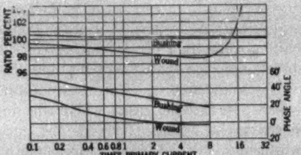

FIG. 5—400 TO 5 RATIO, WOUND, AND BUSHING TRANSFORMERS

Burden 2.5 volt-amperes, 90 per cent power factor

It will also be seen that the ratio of the bushing type transformer varies considerably throughout the range of primary currents and that it becomes very bad at from five to eight times normal current, whereas the wound type transformer has a very small error until the primary current rises to around 20 times normal. This characteristic of the wound type transformer makes it particularly suitable for use on differential protection of transformer banks where the characteristics of the current transformers on both sides of the bank must be carefully matched in order to prevent the operation of the relays on heavy through short circuits.

---

[2] Patent No. 1,550,906.

The upper limit of ratios at which it is desirable to apply the wound type current transformer in circuit breaker tanks is fixed by two considerations. The one is a mechanical, and the other an electrical limitation. The duty required of the circuit breaker for rupturing heavy currents usually varies somewhat in proportion to the current which will normally be carried by the breaker. The mechanical strains placed on the transformer are greatly increased where the circuit breaker is used to interrupt very heavy currents.

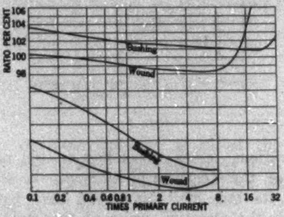

FIG. 6—400 TO 5 RATIO, WOUND, AND BUSHING TRANSFORMERS

Burden, 15 volt-amperes, 90 per cent power factor

This means that even though transformers might be built for heavier primary currents than 400 amperes, their installation in circuit breakers, which are required to carry larger amounts of current, would in many cases be hazardous, because of the severe shocks to which they would be subjected under short circuits and the heavy mechanical forces which would be imposed on them by the explosion when the breaker interrupts the circuit. A second limitation places the 400/5 ratio as a reasonable upper limit for these transformers, because the accuracy of a bushing type transformer of this ratio is approximately as good as that of the wound type transformer.

Figs. 5, 6, and 7 show the comparison between ratio and phase-angle curves of a conventional 400/5 ratio bushing transformer and of the wound type transformer of the same ratio. The curves have been plotted on semi-logarithmic scale so as to condense the portion of the chart beyond full load primary current. The curves in each case were taken without compensating the transformers for the particular burden. This permits direct comparison to be made from one chart to the other to observe the effect of changing the secondary burden on either transformer. These curves show that for a very low burden the bushing type transformer has a better ratio but poorer phase angle than the wound transformer, and that if the burden is increased the wound type transformer has much better characteristics than the bushing type.

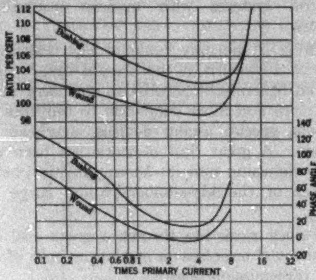

FIG. 7—400 TO 5 RATIO, WOUND, AND BUSHING TRANSFORMERS

Burden, 50 volt-amperes, 50 per cent power factor

## CONCLUSIONS

1. Experience has shown that wound type transformers can be safely installed in the tanks of high-voltage circuit breakers, in many cases, at a very substantial saving of cost over externally mounted transformers.

2. For heavy secondary burdens these transformers can be built to give characteristics that are much better than those of bushing type transformers where the ratios are less than 400/5.

3. For light burdens the wound type transformers offer a means of obtaining characteristics which are suitable for metering at low ratios where bushing type transformers would be entirely unsatisfactory.

# Relation between Transmission Line Insulation
## and Transformer Insulation

BY W. W. LEWIS[1]
Member, A. I. E. E.

DURING the past few years, the great majority of overhead transmission systems in this country have grounded the neutral either solidly or through a moderate resistance.[2] Overvoltages due to arcing grounds on such systems are practically absent. Overvoltages due to switching are in general no longer feared on systems with modern insulation and apparatus.

Lightning is the only cause of high voltage which gives serious concern at the present time.[3] In order to combat lightning, transmission engineers have been adding more and more insulation to the lines as well as various special arcing devices, overhead ground wires, etc. A great deal of work has been done in studying lightning and its accompanying phenomena by means of the klyodonograph and surge voltage recorder.[4]

Laboratory work has thrown a great deal of light on the effect of impulses on insulation, both of apparatus and transmission lines.[5]

The question now arises as to whether, in the light of present knowledge, we can design a transmission line and its connected apparatus so that they will be reasonably safe against breakdown and interference to service due to lightning. Let us first examine the data upon which such a design shall be based.

Sixty-cycle flashover tests on insulators have been made on strings of various numbers of disks. Most of these tests have been made on standard 10-in. disks, spaced 5¾ in. apart. It has been found that the flashover value when plotted against length of string in inches, gives a straight line on log-log paper. The length of string is the spacing per disk times the number of disks. The curve may also be used for insulators of other spacings not differing greatly in proportions from the 10-in. disk spaced 5¾ in. apart. In this case, it is only necessary to multiply the spacing per disk by the number of disks, and enter the curve with the total distance. Table I gives the length of string and 60 cycle flashover for strings of 10 in. disks spaced 5¾ in. apart. The flashover values are plotted against number of disks on Fig. 1.

The impulse flashover of such insulator strings assumes various values, depending on the nature of the impulse, the steepness of its front, the slope and length of its tail, etc. Numerous tests have been made with the standard wave of the High-Voltage Laboratory at Pittsfield on insulator strings of various lengths, and these tests have been repeated with a great deal of consistency.

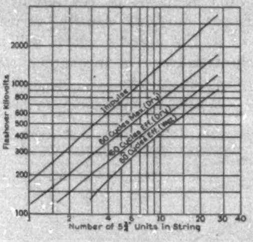

FIG. 1

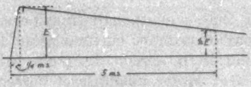

FIG. 2

The Pittsfield wave is a single impulse with a very steep front, rising to its crest value in approximately one-quarter microsecond or less, (depending on the load on the test set), and then decreasing to 50 per cent of the crest value in approximately five microseconds, *i. e.*, the portion of the wave above 50 per cent crest value is approximately one mile in length. This wave is represented in Fig. 2.

The manner of making the tests is to impress on the insulator string such a voltage that the arc-over takes place somewhere on the tail of the wave. The actual

flashover value is determined by adjusting a sphere-gap in multiple with the insulator string until about one-half of the flashovers take place over the insulator string and one-half over the sphere-gap. The setting of the sphere-gap is then taken as a measure of the flashover potential. The values thus determined (Table I), plotted against length of string, again form a straight line on log-log paper somewhat above the 60-cycle values (Fig. 1).

The ratio of the impulse flashover to the 60-cycle maximum or crest flashover is called the impulse ratio.[6] It will be seen that this varies from approximately 1.5 to 2 within the range of the curves. A fair average would be 1.8.

TABLE I

FLASHOVER OF INSULATOR STRINGS BASED ON 10-IN. DISKS SPACED 5¾ INCHES

| No. disks | Length of string inches | 60-cycle arc-over kv. eff. | Impulse arc-over kv. max. |
|---|---|---|---|
| 3 | 17.25 | 200 | 470 |
| 4 | 23. | 255 | 610 |
| 5 | 28.75 | 305 | 750 |
| 6 | 34.5 | 355 | 890 |
| 7 | 40.25 | 400 | 1020 |
| 8 | 46. | 445 | 1150 |
| 9 | 51.75 | 490 | 1280 |
| 10 | 57.5 | 540 | 1410 |
| 11 | 63.25 | 580 | 1520 |
| 12 | 69. | 620 | 1660 |
| 13 | 74.75 | 660 | 1780 |
| 14 | 80.5 | 700 | 1900 |
| 15 | 86.25 | 745 | 2020 |
| 16 | 92. | 785 | 2140 |
| 17 | 97.75 | 820 | 2260 |
| 18 | 103.5 | 865 | 2380 |

If an extremely high potential is applied as compared with the flashover value of the insulators on the tail of the wave, then flashover will take place on the front of the wave. For the particular wave we have been discussing, it has been found that the flashover values thus found are very consistently about 20 per cent greater than the values determined when the flashover takes place on the tail of the wave. For other waves, of course, there may be a somewhat different relation between flashover on the front and tail of the wave.

In actual practise, flashover of insulator strings may take place either on the front of the wave or on the tail of the wave, and sometimes even on the crest of the wave. In case flashover takes place on the front of the wave, then only a small portion of the wave passes on to the rest of the line and station apparatus (Fig. 3A.) When flashover takes place on the tail of the wave, a longer portion of the wave passes on, and as this represents a greater amount of energy, the wave is capable of doing considerable damage if it reaches station apparatus (Fig. 3B). If the value of the wave is not quite sufficient to flash over the insulator string either on the front or the tail, then the full wave will pass on toward the station (Fig. 3C). In each case, there may be considerable attenuation along the line before the wave reaches the station.

Some data have been taken on oil-filled bushings and pedestal type insulators, such as used on disconnecting switches. These data indicate an impulse ratio slightly higher than for line insulators. There appears to be a similar difference of approximately 20 per cent between the flashover value on the tail of the wave and on the front of the wave with the particular wave used in the tests.

During the past few years, numerous data have been accumulated by means of the klydonograph and surge voltage recorder, which has indicated the maximum voltage to be expected on transmission lines with present standards of insulation to be in the neighborhood of 10 to 12 times the crest value of the line to neutral voltage of the system.[4]

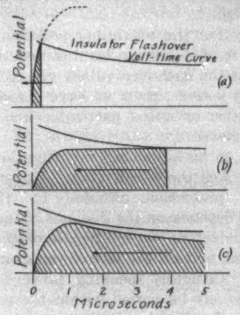

FIG. 3

Table II gives the average number of insulator disks used on actual systems, also the minimum and maximum number of disks for the various standard system voltages, the data being compiled mainly from the *Electrical World Supplement* of January 3, 1925. The impulse flashover value is given also. From this table it will be noted that the impulse flashover value

TABLE II

INSULATION OF ACTUAL LINES

| System voltage kv. | Crest value line to neut. voltage kv. | No. of insulator disks | | Impulse flashover kv. | Ratio impulse to normal voltage |
|---|---|---|---|---|---|
| | | Range | Weighted average | | |
| 66 | 54 | 4–6 | 5 | 750 | 13.9 |
| 88 | 72 | 5–7 | 6 | 890 | 12.4 |

6. *Effect of Transient Voltages on Dielectrics*, F. W. Peek, TRANS. A. I. E. E., Vol. 34, 1915, p. 1857.

is in the neighborhood of 10 to 14 times the crest value of the normal line to neutral voltage. This, together with the results of the klydonograph study, would indicate that the impulse flashover values given in Fig. 1 are fair values to use for the type of impulse which causes flashover on actual systems.

According to Mr. F. W. Peek's investigations, we may take the maximum potential gradient which may be induced on a transmission line by lightning as approximately 100 kv. per ft. of height of conductor. Actually, there have been measured by surge-voltage recorder, potentials which indicate gradients as high as 40 kv. per ft. of height. The readings obtained are subject to the fact that there is no assurance that the surge voltage recorders were located at the point of highest potential. The potentials are naturally limited by the insulator flashover, and such flashover potentials would require gradients in some cases as high as 60 kv. per ft. of height.

Assuming that the maximum potential gradient of 100 kv. per ft. of height can be obtained, and assuming further, that the flashover values given in Fig. 1 are substantially correct, then we have a means of determining whether or not a particular line will be subjected to flashover.

Mr. Peek, in his laboratory investigations, has determined fairly well the effectiveness of overhead ground wires. The protection afforded by the overhead ground wire depends on the distance of the ground wire from the conductors, on the height of the conductors above ground, and on the size of the ground wire and conductors. Generally speaking, however, any one of these factors may be varied within the range of practise without affecting the protective ratio to any great extent. The resistance of the connection to ground also has considerable influence on the protection.

Tables III, IV, V, and VI give comparative protective ratios for various average arrangements of practical transmission lines, assuming ground connections of low resistance. These values have been worked out by Messrs. Peek, Lloyd, and Clem and are based on calculation and tests on laboratory models. It is believed that they are fair values to use, although it is difficult to verify them definitely on actual transmission lines, except by a comparison of operating experience with and without ground wires.[3]

The values in Tables III to VI are given with considerable apparent accuracy, merely for the purpose of bringing out the difference between the various arrangements. However, in using values from the tables for calculations, they should be considered quite approximate.

The tables show ratios considerably greater than can be obtained by calculation with the classical formulas. Mr. C. A. Woodrow has offered an explanation of this as follows:

The potential gradient at the surface of the conductors and ground wire under lightning conditions, greatly exceeds the rupturing potential gradient of air. The air breaks down, forming corona, thus in effect enlarging the diameter of the conductors and ground wire. This, in turn, increases the capacitance between conductors and ground wire and correspondingly decreases the induced voltage on the conductors.

In placing ground wires it is desirable to adhere to the following general rules.

Conductors 6, 5, 4 have same protective ratio as 1, 2, 3 respectively

$$\text{Protective Ratio} = \frac{\text{Voltage with ground wire}}{\text{Voltage without ground wire}}$$

1. The wires should be connected to each tower or connected to ground at each wooden pole.

2. The resistance of the tower footing or the pole ground must be low in order to give the maximum protection.

3. The ground wire should preferably be of the same material as the conductor, or other high conductivity material. This will prevent rusting and will have an appreciable effect in reducing the impedance of the system to line-to-ground short circuits. It will also reduce telephone interference by shunting a good portion of the short-circuit current away from the ground.

4. The ground wires should terminate at the station structure rather than at the first or second tower out on the line. This assures that the last span or two near the station, will be protected, and that there will be no abrupt change in the surge impedance of the line at the terminal of the ground wire. Such a change in surge impedance tends to cause an upward reflection in the voltage of a wave arriving on the transmission line.

The conductivity of the ground wire apparently has very little effect on its protective value, as the protective value depends on the reduction in charge on the line conductors and the increase in capacitance of the conductors to ground, and this is independent of the material of the ground wire. High conductivity is very beneficial, however, in relaying and in preventing telephone interference as previously mentioned.

Now, if we know the potential gradients which may be due to lightning, the flashover value of the line insulators and the protection afforded by overhead ground wires, we are in a good position to determine what must be done to render the transmission line fairly safe from insulator flashover.

In Table VII are given the actual average heights of the lowest conductor at the tower for the various standard system voltages as disclosed mainly from a study of the data given in the *Electrical World Supplement* of January 3, 1925. In this table are given also the potentials which may be obtained with a gradient of 100 kv. per ft. Comparing these potentials with the flashover value of the line insulators in Table II, we see that it is possible to have insulator flashover under the assumed conditions for every system voltage.

TABLE VII
HEIGHT OF ACTUAL LINES AND INSULATION REQUIRED TO PREVENT FLASHOVER

| System voltage | Average height of lowest conductor at tower feet | Possible lightning potential 100 kv. per ft. | Potential with two ground wires conductors horizontally arranged | No. of ins. disks required to prevent flashover | Flashover of insulator disks kv. |
|---|---|---|---|---|---|
| 66 | 35 | 3500 | 1290 | 9 | 1280 |
| 88 | 39 | 3900 | 1440 | 10 | 1410 |
| 110 | 47 | 4700 | 1740 | 13 | 1780 |
| 132 | 47 | 4700 | 1740 | 13 | 1780 |
| 154 | 50 | 5000 | 1850 | 14 | 1900 |
| 187 | 50 | 5000 | 1850 | 14 | 1900 |
| 220 | 56 | 5600 | 2070 | 16 | 2140 |

Assuming the average heights shown in Table VII and a horizontal arrangement of conductors with two overhead ground wires placed above and between the conductors, the potential induced on the conductors will be reduced to approximately 37 per cent of the value without ground wires; *i. e.*, to the values shown in the fourth column of Table VII. Now, in order to prevent flashover, it will be necessary to use the number of insulator disks shown in the fifth column of the table. The insulation required to produce immunity in this manner is considerably higher than the present standard.

Of course, if the conductors were arranged vertically, the situation would be still less favorable. For example, let us assume the heights for top, middle, and bottom conductor shown in Table VIII. Then the potentials without ground wire at 100 kv. per ft. of height would be as given in the third column of the table. Now assume that there are two ground wires placed vertically above the two circuits of a double circuit arrangement. Using the protective ratio given in Table IV, we should arrive at the potentials given in the fourth column of Table VIII. In order to prevent flashover in this case, it would be necessary to use the number of insulator disks shown in the fifth column of this table.

Mr. Peek has found that grading rings, properly proportioned and properly located, will increase the flashover value of a string of insulators, (especially strings containing 10 disks and over), approximately 10 to 15 per cent and this effect may be taken advantage of in reducing the number of insulator disks or in increased factor of safety.

TABLE VIII
VERTICAL ARRANGEMENT OF CONDUCTORS, POTENTIAL INDUCED, AND INSULATION NECESSARY TO PREVENT FLASHOVER

| Conductor | Conductor Height ft. | Potential without ground wires 100 kv. per ft. | Potential with two ground wires 100 kv. per ft. | No. of insulator disks required to prevent flashover | Impulse flashover kv. |
|---|---|---|---|---|---|
| Top....... | 75 | 7500 | 2480 | 19 | 2500 |
| Middle.... | 60 | 6000 | 2340 | 18 | 2380 |
| Bottom.... | 45 | 4500 | 2160 | 16 | 2140 |

It is apparent from this study that the potential induced on a transmission line is independent of the operating voltage, except in so far as the height of the conductors and the number of insulator disks is affected by the operating voltage. In selecting the number of insulator disks, it may not be necessary to consider the extreme potential gradient of 100 kv. per ft. of height. A gradient of 75 kv. per ft. will probably be sufficient to cover the great majority of cases, and a line insulated for this gradient would no doubt be immune from flashover except in rare instances.

Now, what is the situation as regards apparatus insulation, especially transformer insulation. The insulation of power transformers is designed to withstand a certain 60 cycle high potential test, this high potential test being, for fully insulated transformers, two times the line-to-line voltage. The test is applied from high tension winding to low tension winding and ground. In the so-called reduced insulation transformers, which are built for operation with solidly and permanently grounded neutral, an induced voltage test of 2.73 times the leg voltage is given to the transformer windings.

Naturally the designers build into the transformer a factor of safety over the Institute test. Such a factor of safety has been worked out by experience and has proved ample to meet the various switching and arcing ground surges to which transformers are subjected.

With the range of line insulation shown in Table II it has been possible for transformers to be subjected to lightning voltages from 10 to 14 times the normal operating voltage with the average line insulation and more than that with the maximum insulation shown in the table. Such voltages, of course, are subjected to the modification caused by lightning arresters, the capacitance to ground of steel work used in supporting bus structures, etc. Also on any system probably only a fraction of the lightning discharges takes place near stations. However, it is reasonable to suppose that transformers have been subjected many times to ten times normal voltage. Transformers have operated under these conditions with remarkable success, the failures due to all causes including lightning, being only a fraction of one per cent per year.

It is reasonable to conclude that fully insulated transformers with present standards of insulation will operate successfully on systems with present average insulation. If such line insulation is increased, as now seems to be the tendency, then the transformer insulation must be correspondingly increased, unless the present standard line insulation is retained for a reasonable distance adjacent to the station, say, one-half to one mile.

If fully insulated transformers are on a par or slightly stronger than the present average line insulation, then it is apparent that reduced insulation transformers are too weak, as their strength is only about 80 per cent of that of fully insulated transformers. Reduced insulation transformers for this reason have no place on systems subjected to much lightning, unless the adjacent line insulation is correspondingly reduced.

In order to protect transformers now in operation and future transformers with standard insulation, it is recommended that the line insulation adjacent to stations be not increased beyond the values given in Table IX for at least one-half mile from the station.

TABLE IX
RECOMMENDED LINE INSULATION

| System voltage kv. | Recommended 60-cycle arc-over of line insulators—kv. effective | Corresponding number of 10-in. disks spaced 5¾ inches |
|---|---|---|
| 66 | 255 | 4 |
| 88 | 355 | 6 |
| 110 | 400 | 7 |
| 132 | 445 | 8 |
| 154 | 540 | 10 |
| 187 | 620 | 12 |
| 220 | 700 | 14 |

Beyond that point there is no objection to increasing the line insulation to any value required to give good operation. Such a practise on the part of the operating companies will give the manufacturers a definite standard with which to compare their apparatus design.

If for any reason it is desired to increase the line insulation adjacent to the station, then the apparatus insulation should be increased correspondingly.

In cases where it is thought desirable to increase the line insulation and it is feared that maintaining normal insulation near the station will increase the number of flashovers, this may be compensated for by placing additional ground wires over this portion of the line, thereby reducing the potential induced by adjacent cloud discharges to correspond to the reduced number of insulator disks. Such ground wires should extend to the stations and, in some cases, over the stations, in order to insure that the station apparatus secure the full benefit of the ground wires.

The impulse flashover value of standard General Electric bushings is, in general, on a par with the line insulation strength. If a wave gets by the line insulation without flashing over, and reflects to a higher magnitude on reaching the transformer winding, the bushing may flash over and thus offer a means of relieving the transformer insulation. The character and type of waves are so varied that neither the line insulation nor the bushing may be depended upon to protect the transformer in all cases. All that can be said is that if their flashover value is not too high with respect to the transformer strength, there is a pretty good chance that they will flash over and relieve the transformer of at least the greater part of the energy of the wave.

Sometimes power companies call for an especially tall bushing, where the transformer is operated in a district subject to smoke, dust, salt spray, etc. These foreign materials together with moisture reduce the flashover voltage of the bushing. In these cases the long bushing may be used to improve the creepage situation, and the impulse flashover may be kept down to correspond with the transformer insulation by a suitable auxiliary ring or horn gap. Such increased length bushings may afford only temporary relief from creepage as in time dirt will accumulate and their flashover voltage may be reduced to a value comparable to that of a standard bushing. Frequent cleaning may be necessary in either case.

In order to provide a further assurance of successful operation and take care of surges of all kinds, it is necessary to by-pass the incoming surge. The cheapest and most effective present form of such a by-pass, is a lightning arrester.

Mr. K. B. McEachron found that by means of the cathode ray oscillograph, lightning arresters of the oxide film type will hold down the voltage to approximately 1 to 1.8 kv. per cell, depending on the steepness of the wave front.[7] The value of 1.8 kv. per cell corresponds to the standard Pittsfield wave which we have been discussing, and probably also to the steepest waves likely to be encountered in service. Such an arrester, if placed directly at the transformer terminals or as near to the transformer terminals as physically possible, will prevent appreciable reflection and hold down the voltage to a value that is safe under all conditions.

In selecting arresters, the number of cells for a given system is varied, depending on the dynamic overvoltage which may be expected when the load is dropped, in which case the over-speeding of the prime mover and the regulation of the generator may cause a considerable rise in voltage. If this dynamic voltage can be kept to a low value by distribution of load and relaying of the system, or if it naturally comes to a low value owing to the characteristics of generator and prime mover, then a fewer number of cells may be used and still better protection may be secured. This is a very important point and one that should be taken into consideration in all cases.

To summarize: We have shown that it is possible to increase the safety of transmission lines and apparatus from lightning disturbances by adhering to the following principles:

a. Construct the transmission line so that the conductors are as near to the ground as the necessary clearances will permit, and preferably build the line with the conductors horizontally arranged.

b. Install one or two overhead ground wires in accordance with the design of the tower and the requirements for reduction in potential imposed by the height of the conductors.

c. Use sufficient insulation on the line to prevent flashover with the maximum potential gradient that may be obtained with the number of ground wires used.

d. Maintain recommended insulation (Table IX) for one-half a mile or so from the station in order to protect station apparatus. Over this section, additional ground wires extending to the station may be used in order to place this section on a par with the over insulated section as far as flashovers are concerned.

e. Install lightning arresters immediately adjacent to the transformers so as to prevent reflection and hold down the potential to a comparativly low value.

## Discussion

For discussion of this paper see page 1009.

# Rationalization of Transmission System Insulation Strength

BY PHILIP SPORN*

Member, A. I. E. E.

*Synopsis.—Experience on high-voltage transmission lines has shown numerous failures of apparatus which have indicated a decided lack of coordination of the insulation strengths of the various parts of the transmission system. Apparatus offered by manufacturers for a given service shows wide variations in insulation values. Again the flashover and the breakdown values are not at present sufficiently standardized to be comparable among manufacturers of the same piece of apparatus. The standard tests on different types of apparatus are not properly correlated.*

*This paper, besides discussing the above situation, points out the causes for the present status, and indicates the benefits to be derived by grading the insulation on the entire system. Predetermining the point of electrical breakdown on the system in the case of high voltage surges leads most logically to grading the insulation. This grading should result in fewer major service interruptions, with a localization of trouble on a link of the system where repairs can be made easily and inexpensively.*

*The paper points out that additional information is required on surge voltage breakdown of insulation to solve the problem completely but shows that with the present information available a start in grading can be made. The different links in the transmission chain are tabulated according to their relative importance and with this as a starting point, the entire grading scheme is developed to the point of showing relative 60 cycle insulation strength required of the different apparatus used on a transmission system.*

*It is shown: 1, that transmission systems in general, at the present time, are designed without proper consideration from the standpoint of surge voltages which may be imposed upon them; 2, that the grading scheme proposed is possible, although requiring additional operating data and data from the manufacturers to be fully effective; 3, that grading should result in less costly designs and installations; 4, that the net effect will be better performance of the transmission system in service.*

* * * * *

## I. INTRODUCTION

THE idea that it ought to be possible to place insulation strength of the various portions of a transmission system on a rational basis, instead of the present more or less haphazard basis, is perhaps not new, and has undoubtedly occurred to many. It has not occurred to a large enough group, however, or not with potency enough to bring about any action. To the writer the idea first occurred three or four years ago, because the problem was forcefully called to his attention by operating experience. In one particular case, a 23,000-volt belt was placed around a city. The line was well over-insulated; in fact, it was equipped with 45,000-volt pin insulators of an especially liberal design. The following year oil circuit breakers were placed on the loop for sectionalizing purposes. In the first summer of their operation an epidemic of broken bushings on oil circuit breakers, current, and potential transformers broke out. This led to an investigation of the relative insulation values and strengths of the line insulators and of the bushings of the oil circuit breakers and of the current and potential transformers.

In another instance, with a system voltage of 23,000 volts, standard 37,000-volt oil circuit breakers were employed, but the potential transformers and the high voltage metering equipment used on the system was standard 25,000-volt equipment. Here it was found that the trouble was concentrated on the metering equipment and potential transformers, whereas the oil circuit breaker bushings were comparatively free from trouble. On still another system, the transformers employed were not standard transformers but were transformers designed and tested for three times normal line potential instead of the standard double line potential. The insulators, however, employed for insulating the bus and the disconnecting switches, were standard pin type insulators of the approximate rating of the line. Here practically no trouble was experienced with the transformers or their bushings, but a considerable amount of trouble was experienced with the bus insulators due to flashover and breakdown.

All this experience naturally led to the idea that the probable cause of trouble was that a certain part of the system was insulated without regard to the insulation strength of the component parts of the system, and that it was quite possible that the particular part which was heavily insulated was not the right one. This suggested that it ought to be possible to place the entire problem of insulating the various parts of a transmission system on some rational basis, strengthening or weakening either one part or another in accordance with a preconceived and planned system of grading.

Experience gathered since then has shown the desirability of working out some such idea A great deal of this experience has been on a 132,000-volt system. All of it, however, tended to show definitely that some such plan ought to be evolved and that a considerable saving in labor of design and a considerable improvement in the quality of service of the transmission system could be secured if such an arrangement were adopted.

The present paper is to be regarded not as a complete solution but rather an attempt at the beginning of this problem.

## II. PRESENT STATUS IN REGARD TO TRANSMISSION INSULATION

Perhaps no better illustration of the present chaotic condition with regard to insulation strength and ratings can be obtained than by an excursion to catalogs of the various manufacturers. Consider the status among the insulator and bushing manufacturers. In Tables I, II, and III are shown the flashover values of 132-kv., 70-kv., and 45-kv. post type insulators of various manufacturers. The flashovers are in many cases given in the catalog. In other cases they could be obtained only as a sort of special favor. From a surface inspection it will be seen that variations in flashover of from 25 per cent up to 33 per cent are not at all unusual. Yet not all is seen on the surface. Some of the values listed are sphere-gap determinations, others are needle-gap determinations, and still others are given as test values and not as flashover values at all. The manufacturer did not hesitate to give the apparatus a voltage rating; acting on the assumption, presumably, that he was perfectly competent to perform such a function, and that it was not at all necessary for the user of the apparatus to know the basis on which the rating was arrived at. That this indicates a looseness in arriving at ratings is apparent.

| Diameter (in.) | 10½ | 11 | 10¼ | 11 | 9½ | 10½ | 11–1/8 | 12 | 13½ | .. | 10½ |

No better condition exists in the bushing situation, and Table IV shows that up fully. For example, between manufacturer A and manufacturer C on 132-kv. bushings there is more than a 56 per cent difference in wet flashover value, when expressed in terms of the lower of the two values. Obviously there has been no scientific yardstick employed in the determination of ratings of their bushings by the various manufacturers, or else there would not be the discrepancy and variation shown. Tables like this could be compiled to show similar and worse conditions among other groups of insulators; but it is believed that more than enough has been shown to indicate the general fact that the present system of ratings is confusing, chaotic, and, in fact, very often dangerous.

| 33-kv. | 120 | 95 | 155 | 120 | 140 | 112 | 115 | 70 |
| 44-kv. | 160 | 130 | 180 | 150 | 180 | 145 | 140 | 115 |
| 66-kv. | 190 | 150 | 240 | 200 | 215 | 180 | 170 | 135 |
| 132-kv. | 300 | 200 | 375 | 280 | 385 | 330 | .. | .. |

The situation among the apparatus manufacturers may not be quite so bad, but certainly it cannot be called good or orderly. At the present time we have a group of more or less standard voltages on which the design classes are based; but the various groupings of classes are not the same for different classes of apparatus. Further, among these various groupings there are undoubtedly manufacturing classes and these classes may, and probably do, differ from the usage voltage standards. Again, various parts of specific designs are often not correlated and under many existing conditions, cannot be. For example, there are many switch manufacturers who do not make their bushings; there are many transformer manufacturers who do not make them. It is quite obvious that as long as the bushing manufacturer himself is held to no standards in the rating of his bushings, some of that same confusion is bound to creep into the equipment of which these bushings form a part. This, of course, is not meant to imply that such a situation cannot occur and has not occurred, where all the various parts of a piece of apparatus have been made by a single manufacturer. A number of examples came to hand recently in a test of some distribution transformers, on equipment that has been built now for 30 or 40 years, and for such a standard voltage as 2300 volts, it was found in some cases there was 50 per cent variation in the impulse flashover value of the bushings of transformers of various manufacturers. Obviously one cannot conclude from such experience or data that there was ever very much knowledge on the part of some of the designers with regard to the impulse flashover value of the bushing, or that an attempt had ever been made to correlate any such knowledge.

Nor is there any better agreement among the various state regulatory bodies who formulate state rules and regulations, nor between them and the Safety Code.

Each one of these has attempted to lay down a set of minimum standards but there certainly is no unanimity of opinion or of rule as to what such a minimum should be. A glance at Curves 7 and 8 of Fig. 1 will fully bring this out.

One would think that the operating companies, and those designing and constructing for them, would at least have seen the necessity for bringing some order into this whole problem, but it does not happen to be the case. The more one talks with the manufacturers, the more one realizes the predicament in which they find themselves, in attempting to carry out the various ideas of the various organizations with regard to the relative values of insulations of component parts of apparatus. If one examines different practises one finds one system particularly bent on over-insulating its lines, another system practising over-insulating its transformers and having its bushings of normal strength, and still another following reverse practise of having extra heavy bushings and normal insulation on windings. These conditions will be found to exist in the moderate voltages; and in the higher voltages they are sometimes even worse.

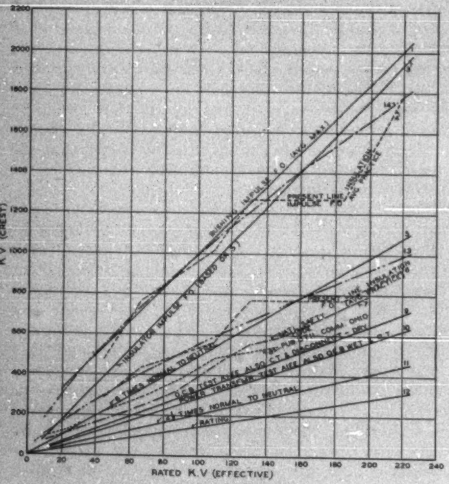

FIG. 1—TRANSMISSION SYSTEM INSULATION STRENGTHS CONDITIONS IN 1927-1928

1 Bushing impulse voltage F. O. (general average)
3 Line insulator impulse F. O. (based on 6 × normal 60 ~ F. O.)
4 Line insulator impulse F. O. (based on present avg. insulation)
5 6 times normal—line to neutral 60 ~ voltage
6 Line insulator 60 ~ F. O. (present avg. insulation)
7 Min. allowable line insulator 60 ~ F. O.—National Safety Code
8 Min. allowable line insulator 60 ~ F. O.—Public Utility Comm. of Ohio
9 60 ~ dielectric test—Oil C. Bs.—C. Ts disconnects—A. I. E. E. dry
10 60 ~ dielectric test power transfs.—P. Ts dry—O. C B. wet—A.I.E.E.
11 2½ times normal line to neutral—60 ~
12 Apparatus rating—60 ~
13 Line insulation (approx. present avg.—60 ~ F. O.)
14 Line insulation (approx. present avg. impulse F. O.)

The effect of this entire situation is to leave one with a general impression that the whole matter is so confused that it would be hopeless to try to change it and bring order into it. In fact, the suggestion has been made at times that in view of the fact that things are working so well on the whole, it is questionable whether a change ought to be attempted; but with this view the writer finds it very difficult to agree. A glance at Fig. 1 makes it all the more difficult.

In Fig. 1, Curve 12 indicates the crest value of various voltage ratings. Curve 11 shows, for various ratings, the crest value of 2½ times normal from line to neutral. This is the maximum value of potential due to an arcing ground on a grounded neutral system where the system is grounded through a resistor below the critical value.[1] In Curve 10 are shown the standard A. I. E. E. test on power transformers, the wet test on oil circuit breakers, and also the dry test on potential transformers. Curve 9 shows the dry A. I. E. E. test on oil circuit breakers and also test on current transformers and disconnects. Curves 8 and 7 show the minimum insulation strengths required by the Public Utility Commission of Ohio, Administrative Order No. 72, and by the National Safety Code respectively. Curve 6 shows the average practise at the present time on line insulation values.[2] The irregularities in practise disclosed by this curve are unusually interesting. Curve 5 is a line drawn through points representing six times the normal to neutral potential. It has been shown[1] that the maximum potential possible due to an arcing ground on an ungrounded neutral system is approximately six times normal to neutral and Curve 5 is introduced here to show the relationship between it and the curve of present practise.

Curve 4 is a translation of curve 6 in terms of impulse flashover utilizing an impulse ratio of 1.8. Curve 3 is curve No. 5 translated in terms of impulse voltage utilizing the same impulse ratio of 1.8; and curve 1 shows the impulse flashover of bushings for various operating voltages. The impulse breakdown of transformers is not given in curve form as the data on this subject are at present far from complete, particularly on transformers that are now in service and that were designed before the importance that is now being attached to the characteristics, as regards impulse strengths, was given much weight. It is known definitely, however, that there are many cases where impulse breakdown voltage is below bushing flashover value; that is, many cases are known where transformers have failed internally without having any flashovers across their bushings. In other words, the bushings failed to give them the protection that they would be expected to give if their flashovers were below the failure point of the transformer itself. It is hard to study the various curves and not come to the conclusion that there is a better arrangement than exists at the present time.

### III. Analysis of the Present Situation

An analysis of just how the present situation came about may be of benefit. The present status is the result of a large number of factors. In the first place the art and the industry have grown tremendously, and at a rate that hardly left time for detailed analysis. This is particularly true with regard to the transmission problem. In this country until 10 or 12 years ago, with the exception of a few isolated cases, the transmission problem was one of no great consequence to the average power company. Most of the territories relied on locally placed plants for their important loads; and what transmission was done was for comparatively unimportant load. Further, the amount of capacity involved and general spread of the system were so small that many of the problems with which we are confronted today were not known, or at least existed only in a much milder form. The development during the past decade of networks with large concentrations of power has taken place under pressure of time. Consequently, it is not at all surprising to find ideas that were developed in one territory were taken over, very often bodily, and applied without proper evaluation, in another territory where an entirely different set of conditions existed, and where the same practise could not be followed with impunity. That undoubtedly has been one cause.

Another cause has been the lack of knowledge with regard to the fundamental phenomena that are causing trouble. The present ideas with regard to lightning and surge phenomena had been known for some time but it had never been possible, except with great difficulty, to secure actual data. Lack of facilities both in money and men to carry out any investigations, except by the isolated few, has resulted in a condition where only the most meager data were available on insulation values of insulators and structures, on the causes of flashover, and on the values to be employed in insulation. There has not yet been published or disclosed, at least in this country, an oscillogram of an actual lightning wave. With lack of actual data, therefore, to prove definitely the nature of lightning and of surges, ample room has been left for theorization, and so a number of theories has arisen and flourished, and many installations and designs have been made on the basis of these with, very often, sad results under operating conditions.

Again, as already stated, some of the old high-voltage systems were isolated neutral systems and the insulation values developed for them were based on isolated system operation. Today practically all of the systems are operated with grounded neutral yet no differentiation has been made in the insulation strengths of the two systems. Perhaps none should be made above a certain voltage, if the line insulation is to be chosen primarily with a view of its lightning flashover, but the point is, that if the line is to be designed from a lightning standpoint, that is, if lightning is to be the predominating factor that will determine the line insulation, that ought to be definitely established and the problem will be so much simpler.

Another phase of the lack of knowledge of the fundamental phenomena causing trouble has been the almost complete absence of data on lightning and switching surges and the trouble that they cause. This has been partially remedied in the last few years by the invention of the klydonograph, but the total information available, which has been properly analyzed, is not even half sufficient.

The result of this lack of data and information has been that even where intelligent design was attempted, the actual execution of such design was not at all easy. This, in turn, has had one direct result—trouble, and generally unexpected trouble. Sometimes it takes the form of extensive line flashover, sometimes of extensive line breakage or conductor burning; sometimes it appears as apparatus failure as in transformers, disconnecting switches, or oil switches. But the trouble will always show up ultimately, and when it does occur there is generally a stirring to find out the cause and remedy.

Typical cases of the kind mentioned are undoubtedly known, but perhaps specific cases will bring home the point more clearly. In one case, a 1500-kv-a., three-phase, 132,000-volt transformer stepping down to 33,000 volts failed through a lightning breakdown on the 132,000-volts, volt side. The high tension coils of one of the phases were completely destroyed. This particular transformer received a factory test according to the standard A. I. E. E. Rules, that is, 265 kv. to ground for one minute and also the standard double induced-voltage factory test. This transformer had a lightning arrester installed on the high tension side. In another case a similar transformer located in an entirely different type of country, failed in one phase of the high voltage windings. The breakdown caused a burning of two widely separate parts of the winding. The arc jumped from the winding to ground in one place and from the voltage ratio adjuster to ground in another. This transformer had no lightning arrester installed on the high side. In both of these transformers no damage was done to the bushings. Obviously, therefore, the bushings did not act as any protective gaps for the transformers. Still another case came under observation on a 30,000-kv-a. auto-transformer bank stepping down from 132,000 to 88,000 volts. Four flashovers occurred between the high-voltage and low-voltage bushings within a short time, doing very little apparent damage to the transformer itself, however, but resulting in each case in a very brief service interruption. On the fourth flashover the corrugations on the low-voltage bushings were broken and the bushing cracked so that it leaked oil and had to be replaced. At the time of the last flashover on this transformer, a klydonograph was on it and the readings showed a potential difference of approximately 850-kv. crest between the two bushings where flashover occurred, and a potential difference of approximately 640-kv. between the corresponding parts of another phase where no flashover occurred. Here was an instance of four cases of trouble without any appreciable visible damage to the transformer. Apparently the bushings acted as excellent protective gaps to the winding.

Instances of trouble on pedestal-type insulators will be cited. In one case a switch insulator on an air-break switch arced over when the charging current of 50 mi. of 132-kv. line was broken through the switch. The same experience was obtained some five months later when the switch was made to perform the same operation.

The history of the Philo-Canton line and the light this has thrown on line insulation practise has already been reported.[3] That this experience is not isolated experience is borne out by the fact that one company this year, after years of operation of a 110-kv. transmission line, has decided to increase the number of ground wires and the insulation on their line.

There are many other cases known which need not be cited. The main thing is, that if operating experience is only investigated far enough, it will be found that there are plenty of data to bear out the fact that there exists ample trouble due to improper insulation strength on our transmission systems, and that this trouble shows up in every phase of the transmission chain. There is bus trouble; there is bushing trouble; there is transformer trouble—for every link in the chain of the transmission system there will be found conditions where breakdowns occurred on that particular link and in many cases the breakdowns occurred on a number of links at the same time.

The difficulty of the situation which generally arises when such a case of trouble occurs is due to the fact that the average transmission system is not a laboratory. Experiments cannot be carried out and the engineer is not allowed, nor should he be allowed, to experiment too widely. The thing that is necessary is to reestablish service, and quickly. The remedy that is therefore applied is chosen from those that can be obtained quickly, and too often the permanency of the cure is in inverse ratio to the speed with which it can be obtained.

What is generally done in a case like that? The apparatus user appeals to the manufacturer, or to a group of manufacturers, for help in the solution of the problem. But it does not follow necessarily that the manufacturer is in a position to give any relief. Often the problem is beyond him, due to the lack of the fundamental data underlying the problem. A part of the blame for this, it is true, rests with the user of the equipment. In the past, equipment has been purchased with practically no attention to its characteristics until operating trouble focuses the attention of the user on those characteristics. The consequence of this has been that in many instances the manufacturer has adopted the attitude that it is a direct reflection on his manufacturing and engineering ability if any question is raised with regard to some of these points, so that today the user finds himself in a position of being unable to get information on characteristics when he asks for it, or to get any sort of guarantee with regard to performance under certain conditions. And yet, if design is to be handled intelligently and if troubles are to be anticipated, all these phases have to be looked into in advance, and that means having the data in advance.

## IV. PROPOSED INSULATION CHAIN

If what has been brought up till now has shown anything conclusively, it should be the fact that properly graded insulation values, rather than haphazard values, are vital and necessary under present conditions. The coming to the foreground of interconnection, with the continued expansion of the amounts of power that will be dependent upon transmission and transmission systems for their proper routing and distribution, combined with the higher standards of dependability, make it imperative that this problem, because of its vital importance to such continuity of service, be solved, and quickly.

The problem, which is one of interest to both the manufacturers and the users of electrical equipment involved in a transmission system, is, however, of greater importance to the users and it would appear logical that they should be the proponents of such a movement. For after all there is a large group of manufacturers making equipment involved in the transmission chain, and each individual manufacturer cannot look out for more than his own particular portion. Often, indeed, different departments of a particular manufacturing group are interested only in their own particular parts of a piece of apparatus. The users of the apparatus, however, have to take care of the combined troubles of all of them, and they are therefore the greatest potential losers under a condition where the various portions are not properly correlated.

The writer believes that grading can be accomplished by a proper study and cooperative effort. It is not necessarily simple, but it most surely can be done. There is no doubt of its importance. But yet it has not been done so far.

Undoubtedly one of the causes that have blocked rationalization of insulation in the past has been the fact that the rating of apparatus has been by voltages and very often the voltages were differently divided on the different classes of apparatus. Further, the rating while probably conforming to A. I. E. E. tests had very little else as a basis for the establishment of the particular rating. It is conceded that the A. I. E. E. test is lacking in many respects since it leaves open to the manufacturer phases of design which have a material effect on its performance on the line. In many cases, as already pointed out, these data are not known even to the manufacturer. Again, one of the causes that has blocked rationalization has been hard economics. To illustrate, if a given 44,000-volt system had to contend in a certain district with conditions of service that were at least as hard on apparatus as a 73,000-volt system in some other district, it is difficult for the designer to bring himself to the point where he will specify 73,000-volt equipment if he is not to appear extravagant, particularly to his executive superiors. Yet in that case, what it is really necessary to specify is insulation strength and not voltage at all.

---

[3] *Lightning and Other Experience with 132-Kv. Steel Tower Transmission Lines*, Sindeband and Sporn, A. I. E. E. TRANS., Vol. 45, 1926, p. 770.

All this can be overcome by dividing insulation into classes, each class to contain the whole series of links used in the transmission chain and the entire series properly graded. This will be elaborated upon further. The idea, however, is sound. Our experience with 132-kv. system has already been cited. We have had experience with 66,000-volt systems which, while not proving conclusively, indicates fairly well that there is a possibility of designing a system so as to be practically free from insulation troubles.

### V. Fundamentals of the Problem

Before considering the detailed analysis of the various insulation classes it might be well to consider the causes of flashover. An insulator will flash over to ground or to another member when the voltage to ground, or to the other member, is greater than the insulating value of the insulator plus the supporting structure from the live point to ground or of the insulator plus intervening space to the other member. Broadly, this covers also cases of puncture. These overvoltages may be of several types and of several sources of origin:

1. A straight overvoltage at the power frequency caused by a system running away, by the crossing of circuits of various potentials, or by some other unusual occurrence.

2. An overvoltage may appear due to arcing grounds. This voltage may have a frequency of the order of thousands of cycles. Except for the isolated neutral systems which are rare today it will, of course, not appear.

3. Overvoltages may take the form of impulse voltages and these, in turn, may be caused either by switching or by lightning.

It has already been shown (1) that where a system is grounded, even with a considerable amount of resistance, the voltage due to an arcing ground can be only of the order of two and a half times the line to neutral voltage. The cases of conditions of overvoltage due to running away of machines, etc., are extremely rare. Excluding, therefore, the cases of arc-overs due to particularly bad local conditions such as particularly bad conducting dust or soot, we get as the principal cause for flashover, impulse voltages. The switching surges will, at the maximum, be of the order of five and one-half times normal, but voltages so high will be very rare, which means again that the principal high voltages to insulate for are the voltages due to lightning.

| 28 | Disconnect — transformer side O. C. B. |
| 29 | Insulator—transformer side disconnect |
| 30 | Power transformer H. T. bushing |
| 31 | Power transformer H. T. winding |

Let us consider a power system transmission chain, list all the apparatus and equipment and, if possible, see whether or not a definite system of grading cannot be worked out for the various insulation members.

In Fig. 2 there is shown in diagrammatic form the various portions of such a chain. Fig. 2 as it stands, is representative of a typical high-voltage generating station with a generator and a transmission line connected to the bus. It will be seen that some of the parts have been rather finely subdivided in Fig. 2, the reason being that it was thought that, in the first analysis, it would be best to go the limit in the subdivision of parts, and later consolidate such members as could be placed in the same class.

If the generator shown on the low side of the transformer in Fig. 2 is taken away and a low-voltage bus substituted for it, then Fig. 2 becomes the typical diagram for a combination switching and stepdown substation, and if the entire upper half of the diagram is taken away, Fig. 2 becomes a typical switching station diagram.

Before a complete analysis and solution of the problem is possible, it will be found necessary to have further data:

1. It will be necessary to have definite power-frequency flashover values. The methods of obtaining these values should be more rigidly prescribed than at the present time. The methods of measuring at the present time are not rigidly enough prescribed and too great variations in the values of practically identical apparatus exist in the figures of different manufacturers.

2. It is necessary to have definite data on the lightning flashover. In this connection it is essential that a standard lightning wave be established at present. Until complete and exhaustive studies with the Dufour oscillograph show definitely what lightning is, it is essential, if confusion is to be avoided when the lightning or impulse flashover is discussed, that it mean a definite thing. This will clear up the present situation where each manufacturer or each laboratory man is his own lightning maker, and utilizes his own ideas as to what constitutes a lightning or impulse wave. A method of measuring this particular wave should be definitely agreed upon. If so much is accomplished, it should be possible to go one step further and reach a definite understanding with the manufacturers that such data are necessary for design and that they agree to furnish such data to the users of their equipment.

3. More work will have to be done on the characteristics of switching surges. Numerous data are available now with regard to the magnitude of switching surges but further data are needed with regard to their frequency or their characteristics, and as to whether their effect on insulation approaches more closely to that of lightning or impulse wave, or more closely to the power frequency.

4. More data are necessary on the protective features of the design of the stations themselves and particularly on the protective effects of various possible incoming line arrangements, of arrangements of apparatus with regard to structure, and on the protective values of lightning arresters.

## VI. PROPOSED SYSTEM OF GRADING

In Table V there has been set up a proposed system of grading for every member shown in Fig. 2, considered as a generating station, as a straight switching station, and as a step-down and switching station. In the setting down of orders of importance certain assumptions have been made. These are as follows:

1. That the station has two buses.

2. That there is a transfer or inspection oil switch available at the station.

3. That in case of a lightning impulse or discharge coming into the station, which is sufficiently high to spill over, the spilling over at one point or on one piece of apparatus will prevent the impulse with a dangerously high head going any further; that the first spillover would afford sufficient relief, and that the rest of the equipment beyond that point would not be subject to spillover.

4. The effect of a change in the entrance arrangement of ground wires, the effect of the protective values of the bus structure itself, and the effect of the lightning arrester have been entirely neglected. This may be unfair to the lightning arrester, perhaps, but it was felt that for the purpose of the study it would be best to consider the lightning arrester as an additional

safeguard, rather than as a means of definitely reducing the value of the impulse voltage to which apparatus may be subjected.

Referring again to Table V, columns 2, 3, and 4, consider the high-voltage generating station from viewpoints A, B, and C. In the case of viewpoint A it has been assumed that the source of the high-impulse voltage is the transmission and that it becomes lower as it travels into the station. This, of course, takes no account of reflections and re-reflections but it is necessary to do that if the problem is to be considered at all. Viewpoint B is based on the assumption that if an insulator on the bus fails a complete interruption will result. The installation of bus sectionalizing switches, however, results in no such complete interruption. In that case, however, instead of considering the bus as a whole, if the problem is confined to a particular bus section the assumption just made still holds true. In C it has been assumed that the most expensive piece of apparatus to repair on failure is the power transformers and that in general when an oil-filled piece of apparatus such as the current or potential transformer, is damaged, then it will generally be a more expensive matter to repair than the damage to a mere insulator on the disconnect switch.

With these assumptions known, it is plain why, in the case of column 2, the highest insulation value has been assigned to the member 21, and the lowest to member 31. In the case of column 3 on the other hand, it can be seen why the highest insulation strength has been assigned to member 1 and the lowest to member 21. In the case of Column 4, the highest insulation strength has been assigned to member 31 and again the lowest strength to 21. It is not believed necessary to go into a detailed explanation of the reason for the relative order of the intervening members as it is felt with the explanation of the assumptions and the basis of reasoning employed the remaining positions will be obvious upon study. Columns 5, 6, and 7 analyze the order of insulation strength for a switching station from the viewpoints A, B, and C respectively, and Columns 8, 9, and 10 show a proposed grading system for a combined step-down and switching station from the same points of view also, that is from points A, B, and C.

Examining Table V a little more carefully, one will see that the order of grading for a particular point of view is not very different for the various stations; that is, it is practically the same for the generating station as for the switching station, and altogether the same for the generating station and the combined step-down and switching station. Obviously Table V does not offer, as it stands, a practical setup. There are altogether too many members and it is not conceivable that a grading system could be worked up with 31 members and yet have a practical difference in insulation values between them. In Table VI the total number of 31 members has been reduced to 15 and values assigned to each member on the basis of its position in Table V. These are shown on columns 1, 2, and 3. In column 4 the position numbers of a particular member in columns 1, 2, and 3 has been averaged and on the basis of that average a suggested arrangement for general conditions has been worked out in column 5.

An inspection of column 5 reveals an interesting setup. It shows that from the standpoint of general minimum disturbance and minimum damage to the system, the internal make-up of the oil switch ought to be the strongest, that the bus insulators ought to come next and the power transformer windings next, the oil switch bushing next in strength and so on until we get to the insulation of the gaps on the lightning arresters which ought to be lowest down in the series. It shows further, for example, that in general the power transformer bushings ought to occupy a place two-thirds down toward the low end of the insulation chain as against the first position that they undoubtedly occupy on many systems today. It shows that while the line insulators are not to be the very lowest in insulation value they should be very close to that, their position in

TABLE VI

GRADING INSULATION FOR LIGHTNING IMPULSE SURGES

1 = Highest insulation down to 15 = Lowest Insulation for Results Indicated

| Column | | 1 | 2 | 3 | 4 | 5 |
|---|---|---|---|---|---|---|
| Member | Apparatus | Min. no. of interruptions | Min. danger of complete interruptions | Min. cost of apparatus repair | Ave. position from columns 1—2—3 | Suggested for general conditions |
| A | Oil switch (internal make-up) | 13 | 4 | 2 | 6-1/3 | 1 |
| B | Insulators—Bus side of oil switches | 10 | 1 | 9 | 6-2/3 | 2 |
| C | Power transformer windings | 15 | 5 | 1 | 7 | 3 |
| D | Oil switch bushings | 12 | 3 | 6 | 7 | 4 |
| E | Potential transformer windings | 9 | 9 | 3 | 7 | 5 |
| F | Disconnects—Line side of oil switches | 3 | 7 | 11 | 7 | 6 |
| G | Insulators—Line side of oil switches | 2 | 8 | 12 | 7-1/3 | 7 |
| H | Current transformer windings | 7 | 11 | 4 | 7-1/3 | 8 |
| I | Disconnects—Bus side of oil switches | 11 | 2 | 10 | 7-2/3 | 9 |
| J | Power transformer bushings | 14 | 6 | 5 | 8-1/3 | 10 |
| K | Potential transformer bushings | 8 | 10 | 7 | 8-1/3 | 11 |
| L | Current transformer bushings | 6 | 12 | 8 | 8-2/3 | 12 |
| M | Insulators on line | 1 | 15 | 15 | 10-1/3 | 13 |
| N | Choke coils | 5 | 13 | 13 | 10-1/3 | 14 |
| O | L. A. sphere-gap insulators | 4 | 14 | 14 | 10-2/3 | 15 |

the table where the lowest value is represented by 15, being 13. Finally this establishes in general an order of insulation strength from which some practical setup can be made.

TABLE VII
PROPOSED INSULATION CHAIN

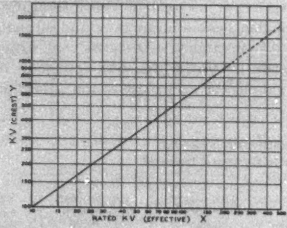

FIG. 3—TRANSMISSION LINE INSULATION BASED ON PRESENT PRACTISE $Y = 18.3\,x^{0.742}$

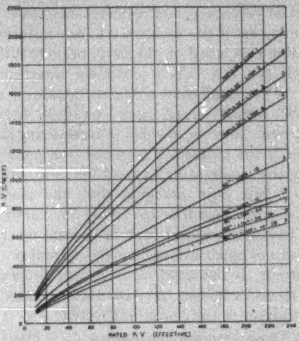

FIG. 4—PROPOSED GRADING OF TRANSMISSION SYSTEM INSULATION STRENGTHS

Showing impulse and 60-cycle flashover or breakdown voltages. For references to links, see Table VII

This has been done in Table VII. Here the 15 members of Table V have been consolidated into four groups and it will be noticed that the grouping in Table VII follows almost entirely the order indicated in Column 5 of Table VI, the one exception being that of the insulation of the line itself. Table VII then proposes that the insulation on a transmission system should be divided into four groups and that the insulation of these groups follow a definite order,—that the insulation of the oil switches and the bus should be highest and the insulation of the line should be lowest. (By line insulation is meant of course only that portion of the line which can be considered from the standpoint of the substation itself. Obviously the insulation of the remainder of the line is an independent problem in economics. If sufficient money is spent, sufficient line insulation can be provided to prevent even the highest lightning voltage from flashing over. This phase is of course not considered here.) Table VII further suggests that the insulation of a group of members in the transmission system consisting of oil switch bushings, potential transformers, disconnect switches, current transformers, etc., be all held at the same level. These four groups are subsequently referred to as the four links.

## VII. PROPOSED INSULATION SYSTEM

In Fig. 3 the data of curve No. 6 of Fig. 1 have been plotted on logarithmic coordinates and a balanced straight line drawn through the values. The equation of this line is

$$Y = 18.3\,x^{0.742} \tag{1}$$

where $Y$ = the crest value of flashover in kv.,

and $x$ = r. m. s. of the line voltage in kv.

The same curve is plotted on regular coordinates as curve 13 in Fig. 1. Using an impulse ratio of 1.8 we get curve 14 in Fig. 1 as the impulse flashover value of line insulators for average present practise. The equation of this curve is

$$Y_i = 32.9\,x^{0.742} \tag{2}$$

Where $Y_i$ is the impulse value and all other values are the same as in equation (1).

In Fig. 4 curves No. 1 to 4 have been proposed for grading the four links shown in Table VII. These curves represent the breakdown or flashover values of the various links and are based on the following:

a. Starting out with curves No. 4 as 100 per cent the other curves have been raised by 10 per cent in terms of curve No. 4 so that curve No. 1, for example, represents at every point 1.3 times the values in curve No. 4.

b. The line insulation developed in Fig. 3 and shown as curves 13 and 14 in Fig. 1 has been adhered to for the insulation of that portion of the lines affecting the substations. On the assumption that a 20 per cent differential would be allowed between the insulation of the line adjacent to the substation and the insulation of the line proper this made curve 14 of Fig. 1 and curve 2 of Fig. 4 identical.

c. Curves 1 to 4 in Fig. 4 do not take into account 60-cycle strengths or tests.

The development of 60-cycle strength has, however, been carried out in curves 5-9. These are based on the impulse strength shown in curves 1-4 and the relationships are as follows:

Curves 9, 5, and 6 give the 60-cycle strength of link 1, parts A, B, and C respectively.

Curve 8 gives the 60-cycle strength of link 2.

Curves 8 and 9 give the 60-cycle strength of link 3, parts A and B respectively.

Curve 7 gives the 60-cycle strength of link 4.

The values of 60-cycle strength are based upon the best available information at the present time on impulse ratios. Where the 60-cycle strength of a particular link has been split into two or more parts, this was done because the different members naturally had different impulse ratios. This clearly shows up the fact that while rationalization is possible for insulation value on the basis of lightning strength and while it may be possible to reduce the number of links in an insulation chain to as low a value as 4, as soon as 60-cycle strength is considered the problem becomes more complicated, the reason being, of course, the different impulse ratios of the different classes of material. The determination of the ratios employed will be evident from an inspection of the curves.

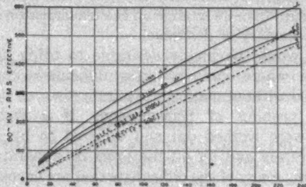

FIG. 5—60-CYCLE EFFECTIVE VOLTAGE BREAKDOWN OF LINKS AND A. I. E. E. TEST SPECIFICATIONS

In Figs. 5 and 5A the curves of 60-cycle strength developed in Fig. 4, have been transposed and plotted in terms of r. m. s. values on both coordinates. The A. I. E. E. tests corresponding to apparatus represented by link 3-A are shown in curve No. 2 (dotted) by links 2-A and 3-B in curve No. 5, by links 1-A and 1-C in curve No. 8, and by link 3-B in curve No. 10 (dotted). In analyzing these curves it will be seen that while it is possible to rationalize and to work out a system of insulation strength with comparatively few links in a particular chain the problem is not quite as simple when the 60-cycle strength is considered. Further, it is definitely clear that in so far as present A. I. E. E. tests are concerned, the buying and specifying of equipment on the basis of these tests will result in a system of insulation that is far from rational as far as impulse or lightning strength is concerned. It shows again that if a system such as proposed in Fig. 4 were adopted, in voltages up to approximately 150 kv. a considerable increase in 60-cycle strength and test is necessary if the proper impulse strength is to be obtained on equipment such as transformers. This may appear objectionable and will naturally be raised as an argument against the system but the objection is valid only so long as present systems of design are followed. As soon as it is definitely recognized that strength in two directions is required, the designer of equipment will be in a much better position than he is today, for he will be able to design for requirements of actual line service rather than along the present lines, where he designs for one thing, *i. e.*, 60-cycle strength, whereas what is needed is impulse strength.

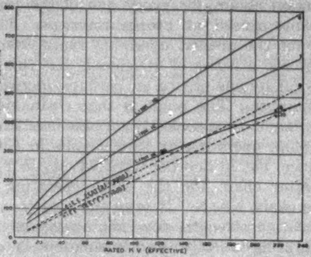

FIG. 5A—60-CYCLE EFFECTIVE VOLTAGE BREAKDOWN OF LINKS AND A. I. E. E. SPECIFICATIONS

A thorough revision of the standards with regard to 60-cycle strength and 60-cycle tests, will be necessary before complete rationalization can be accomplished. No attempt will be made to attack this particular problem at this time. Leaving, however, the 60-cycle tests as they are, it should still be possible to work up a rationalized system of insulation strength under impulse conditions and it should be unnecessary, if the system is a proper one, to disturb it in any way when finally the 60-cycle end is rationalized.

Keeping this in mind, the writer suggests the system shown by curves 1 to 4, Fig. 4, as fulfilling the necessary requirements. Mention has previously been made of the fact that as long as apparatus and insulation strength are specified and bought on the basis of normal or line voltage, difficulty will be encountered in utilizing on a system of a definite voltage, apparatus that might have a nominal rating of a considerably higher voltage. This difficulty could definitely be avoided if apparatus were bought on the basis of normal operating voltage and with insulation strength of a certain definite chain. To amplify: suppose, referring again to Fig. 4, a series of insulation chains were drawn up as shown in Table VIII. This table offers a series of insulation chains for every one of the four links, with chains spaced at proper intervals. The table suggests for the present operating range from 25 kv. and upwards, a series of 10 chains, but this number could be cut by one or two or, perhaps, increased by a similar number. The point is that chain No. 4, for example, might be a perfectly suitable insulation chain for a system operating at 69,000 volts in California, for instance, but in another territory, say in Florida, a much better chain for the same operating voltage might be chain No. 5. If once the idea is embraced that insulation strength does not always go together with operating voltage and insulation is specified independently of operating voltage, then it will be possible to realize the ideal of obtaining, for each system, the insulation strength really necessary. In Table VIII nominal kilovolt classes have been purposely indicated but there is really no valid reason why these should be adhered to or why these should appear in any specifications or in any of the design calculations.

TABLE VIII
IMPULSE VOLTAGE FAILURE FOR PROPOSED INSULATION CHAINS

| Insulation chain no. | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 |
|---|---|---|---|---|---|---|---|---|---|---|
| Nominal kv. class | 25 | 37½ | 50 | 70 | 90 | 115 | 145 | 175 | 205 | 237½ |
| Link no. | All values below in crest kv. | | | | | | | | | |
| 1 | 382 | 526 | 639 | 819 | 985 | 1185 | 1405 | 1620 | 1830 | 2020 |
| 2 | 353 | 486 | 592 | 756 | 910 | 1095 | 1296 | 1495 | 1686 | 1870 |
| 3 | 324 | 445 | 542 | 693 | 834 | 1005 | 1190 | 1370 | 1548 | 1715 |
| 4 | 294 | 405 | 492 | 630 | 757 | 912 | 1080 | 1245 | 1405 | 1555 |

## VIII. PRACTICAL APPLICATION OF SYSTEM AND RESULTS EXPECTED

If a system of insulation such as proposed in Table VIII or a similar system were adopted, it would result in benefits in many directions. Among these are:

1. The problem of designing the insulation for a system would be considerably simpler than it is at present. Once having decided on the insulation strength necessary on one of the important links, the particular chain into which the entire system insulation is to fall would be determined automatically. The problem of specifying the insulation for the various pieces of apparatus would then become one of simply specifying a certain definite insulation chain.

2. From the purchasing of apparatus standpoint it would mean the placing of the various manufacturers on a more even competitive basis. It would give greater assurance of getting the best purchase for a given amount of money.

3. The establishment of a definite number of classes will result in simplifying and reducing the number of insulating units and insulating classes offered, and will therefore result in a reduction of cost with benefits both to the manufacturer and to the user of apparatus.

4. Without treating every substation insulation problem as a special problem to be long studied, it would be possible to get a correct solution and one that would be reasonably certain to work right under practically all conditions in so far as insulation is concerned.

5. The final effect of all the above would be a great improvement in the type of service rendered by the transmission system.

## IX. SUMMATION

The problem of rationalizing the transmission system insulation is greater than can be covered within the scope of one paper. The writer believes, however, that he has shown that:

1. The present status with regard to insulation practise and standards is not satisfactory. This is as true with regard to the manufacturing of apparatus, the application of apparatus, as it is with regard to the various rules and regulations issued by state and other regulatory bodies.

2. There is no single cause for the present situation, but there are many contributory factors, some of which were perhaps unavoidable.

3. The net effect of the present status is one of confusion in regard to the specification and the purchase of insulation value. Further, the problem of designing a system that is properly correlated in insulation strength is extremely difficult. This results, in the long run, in more trouble on the transmission system than is necessary or desirable.

4. It would be highly desirable to bring about a condition where some of these difficulties could be eliminated without making a separate research problem of each problem of transmission. If a system of grading were worked out and adhered to by all the manufacturers and by all the users of apparatus and equipment, many of the difficulties that are encountered today in the problem of making the transmission system give continuous service would be done away with.

5. Before such a state can be reached it will be necessary to obtain considerably more information or data bearing on the problem. It will be necessary to have more exact data with regard to the characteristics of switching surges and of lightning waves, and a definite agreement as to how these various quantities are to be measured,—in other words, standards for each.

6. Assuming that all the data outlined in 5 are

obtained, a method of arriving at the order of grading of insulation can be formulated. A specific system was actually worked out. It is possible by proper consolidation of various members to reduce the links in a transmission chain that will be graded from each other to a reasonable number. A system composed of four links was proposed. While four links are adequate from a lightning standpoint, from the power frequency standpoint the problem is considerably more complicated due to the different impulse ratios. This problem will require further study.

7. Without changing for the present the specifications covering power frequency strength, a series of insulation chains can be worked out that will be properly graded from the standpoint of lightning strength. A definite series of that type was proposed. By elimination of nominal operating voltages the probability of obtaining proper insulation strength will be enhanced in many cases.

8. If the systems proposed are adopted the ultimate result ought to be less expensive and more satisfactory design, in other words, better continuity on the transmission system as a whole.

Acknowledgment is due to Mr. I. W. Gross for his help in preparing some of the data and in drawing up the numerous charts and tables.

# Discussion

## RELATION BETWEEN TRANSMISSION-LINE AND TRANSFORMER INSULATION

(Lewis)

## RATIONALIZATION OF TRANSMISSION-SYSTEM INSULATION STRENGTH

(Sporn)

New Haven, Conn., May 9, 1928

**V. M. Montsinger:** The authors of these papers have pointed out the desirability of setting up standards for grading the various apparatus according to their impulse-voltage strengths and have shown the haphazard way in which this work has been done in the past. Their plea for a more rational method should receive very careful consideration.

I do not believe that there is any argument as to whether or not the relative values of the insulation of transformers and the various adjacent apparatus should be put on a more rational basis. The important question is how shall the grading be done? There are two phases to this problem. First, what should be the difference between, say the transformer impulse strength and the arc-over strength of the adjacent line insulation, etc.; and second, what is the most convenient and practical method of expressing the impulse strengths or the relative strengths of the various apparatus?

It is from the second standpoint only that I wish to discuss these two papers. I shall for the sake of simplification confine my remarks to transformers and adjacent line insulators.

Naturally, the first thing that the operating engineer asks for is the impulse breakdown values of the transformer windings and the flashover values of bushings and line insulators. It is, of course, well known that the impulse breakdown of insulations, either of solids, oil, or air, is dependent entirely on the kind of wave used and whether breakdown occurs on the rising front at the crest or at some point beyond the crest, generally called the tail of the wave. Therefore, for the impulse strength to mean anything at all it is necessary to define the wave. A standard wave, of course, could be set up but it would mean that everybody who desired to make a test must have the same kind of a lightning generator, which of course is impractical. Furthermore, it is not practical to test a transformer winding with impulse voltage to check its impulse strength. Neither is it desirable to subject a winding to an impulse voltage in value anywhere near its failure point on account of the possibility of causing injury which might not show up until after being placed in service. Therefore, it appears that we must look for some other more satisfactory method.

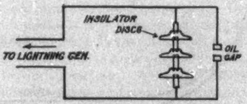

Fig. 1—Set-Up for Comparing Breakdown of Oil and Arc-Over of Disks on Front and Tail Impulse Wave

Let us consider first the adjacent line insulators and their characteristics with respect to impulse flashover at different points on the wave. Tests conducted with Mr. Peek's lightning generator have shown that within practical limits the flashover impulse ratio of an insulator varies with different waves in about the same order as does the breakdown of insulations.

To illustrate what I mean a typical case will be given. Fig. 1 herewith shows an oil gap shunted with three standard 10-in. disks. When an impulse voltage, whose maximum value was approximately twice the flashover value of the insulators, was imposed, the disks naturally cut off the wave, provided the oil-gap setting was not too close. The oil gap was then adjusted to cause one-half of the breakdowns to occur across the oil gap. Sphere gap measurements showed that the disks limited the wave to about 600 kv. The oil gap was then widened and the imposed wave lowered until flashover did not occur until a point beyond the crest of the wave had been reached. To cause one-half of the breakdowns to occur across the oil gap the electrode had to be brought back to practically the same setting as before. The maximum value of the wave in this case was around 450 kv. as determined by sphere gaps. The time in the two cases ranged from a fraction of a micro-second to several micro-seconds. Similarly the same phenomenon was found when solid insulation was used in place of the oil gap.

This, of course, means that a string of insulators can be used as a yard stick for comparing or expressing impulse strengths of transformer windings. Or, in other words, if we know the proper relation between the impulse strength of a given number of line insulators and a given voltage transformer, it is not necessary to know or to give the impulse values of either.

Furthermore, it would eliminate the necessity of defining the wave, for the reason that if the proper relationship is known on one part of the wave approximately this same relationship holds for another part of the wave. Of course, there is a limitation to this in that the two curves of impulse strength versus time are not exactly parallel but cross and diverge as the waves approach the 60-cycle peak value as shown in Fig. 2 herewith.

If all insulator disks had the same spacing it would be satisfactory to express normal line insulation in terms of the number of disks. However, since the spacing of disks may vary considerably, some being as low as 4¾ in., while the standard spacing is 5¾ in., and since both the 60-cycle and impulse flashover strengths of a string of insulators is within reasonable limits a function of the vertical height, and furthermore since both the dry and wet impulse strengths are the same, it is entirely practical to express line insulation in terms of 60-cycle dry arc-over values. This enables any manufacturer or operating company to check the tests.

Referring to the recommended line insulation in Table IX of Mr. Lewis' paper, it will be noted that the 60-cycle arc-over is considerably higher than the 60-cycle tests on the transformer corresponding to twice line voltage plus 1000 volts. This does not mean from the standpoint of impulse voltages the arc-over of the insulator is stronger than the transformer windings, for the reason that the impulse ratio of breakdown of air is considerably less than the impulse ratio breakdown of transformer windings. This difference plus the factor of safety between the tests and actual breakdown of windings makes the transformer stronger than the recommended line insulators. This applies, of course, to fully insulated and not to 2.73 or reduced insulation transformers. In fact, experience has shown that fully insulated transformers have given very satisfactory service when used with normally insulated lines.

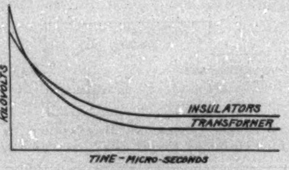

FIG. 2—VARIATIONS OF IMPULSE STRENGTHS OF INSULATORS AND TRANSFORMER INSULATIONS

So far as the transformer is concerned the insulation in the windings should also be given in terms of 60-cycle tests. The reason why this can be done is because many tests have shown that very nearly the same impulse ratio holds for oil alone, puncture of solid, puncture of combinations of oils and solids, creepage over solids, and finally, breakdown of transformer windings, either of interleaved type or concentric type. It is indeed fortunate that this is so; otherwise, if the different insulations and different arrangements of insulation gave widely different impulse ratios it would be an impossibility to express the impulse strength in terms of 60-cycle tests. Not only should it be expressed in terms of 60-cycle voltage but the transformers should be so tested. This makes it possible for all manufacturers to be on a fair and comparable basis and assures the customer of what he is getting.

The impulse strength of the transformer bushings and terminals can be expressed also in terms of 60-cycle dry flashover if it is desirable to grade its impulse strength in reference to that of the other apparatus.

In summing up, the main point which I wish to bring out is that it is not practical and, in fact, not necessary to attempt to give impulse values for the strength of transformer windings and the impulse flashover values of bushings and insulators, but that the desired purpose is accomplished in a more satisfactory manner if 60-cycle dry flashover values of insulators can be standardized as the yard stick for judging the impulse strength of the transformers.

**W. L. Lloyd, Jr:** The subject of rationalization of insulation is not a new one. However, the limited knowledge available (for example, *The Effect of Transient Voltgages on Dielectrics*, F. W. Peek, Jr., TRANS. A. I. E. E., Vol. XXXIV 1915, Part II, p. 1857) has not been utilized as fully as its importance warranted.

Developments have been rapid in the last few years due to a realization that lightning is not a mysterious phenomenon, but that it is a definite thing that can be discussed in an engineering way, studied in the laboratory, and guarded against in the field.

As has been pointed out in the papers, laboratory work and field experience in general show that it is important to design a line so that the conductors are as near to the ground as possible, and that high towers and badly exposed places should be avoided. Similarly, horizontal spacing is preferable to vertical spacing since the average lightning voltage induced on the line is less with horizontal spacing.

Ground wires properly installed and longer insulator strings out on the line can be employed to eliminate flashovers or to reduce their number. Grading-shields or grading-rings on the insulator strings, by raising somewhat, in effect, the lightning sparkover voltage of the insulator string, can be utilized to reduce further the number of flashovers, and prevent damage to the insulators when a flashover occurs.

Long insulator strings should not, however, be brought right up to the station. For a half mile or so from the station recommended insulation should be employed to limit the lightning voltages impressed upon the station equipment. Where dirt or leakage conditions are bad in the vicinity of the station the lightning voltage applied to the station equipment can be more satisfactorily limited by low-set rings on the long insulator strings or by a short air-gap in parallel with the string. To prevent an excessive number of flashovers across these shorter insulator strings, low-set rings, or paralleled gaps, the number of ground wires should be increased over this short section of the line. The proper number of ground wires will give the same factor of safety on this short section of the line with reduced insulation as on the main section of the line with increased insulation but with fewer ground wires. Lightning arresters, if used, should be placed as close to the transformers as possible. The transformer insulation should be stronger than the sparkover voltage of the bushings or the protective gaps at the station.

As suggested by Mr. Montsinger, the strength of the transformer, the sparkover of the bushings, the setting of the gaps, and so forth, should preferably be expressed in terms of the sparkover voltage or number, of standard 10-in. diameter, 5¾-in. spaced, insulator disks, since then any discussion of the shape of the wave, when sparkover takes place, and so forth, does not enter. In this way the laboratory work should be most advantageously utilized by the largest number of operating engineers and we can, at last, proceed with a logical and rational insulation of our transmission systems as we have been attempting to do for so many years and as urged again by Mr. Sporn.

**C. L. Fortescue:** Recent investigations both in the field and in the laboratory indicate that the lightning surge is of appreciable duration. It is estimated that the duration of the effective portion of the wave may vary from a few to 100 microseconds, the longer wavelength having crest values below the 60-cycle flashover of the insulators. Mr. Torok's investigations on the phenomenon of flashover between sphere gaps shows that the speed of propagation of the streamers from sphere to sphere is of the order of one-tenth the velocity of light. Similar tests in connection with strings of insulators indicate a speed of propagation over the length of the string of the order of one-fiftieth the velocity of light. These figures are necessarily approximate and may be subject to modifications as a result of further investigation. However, the results indicate that the time required to complete a flashover due to a surge, after the 60-cycle flashover point has been reached, is, for a string of insulators, of the order of a fraction of a microsecond. Fig. 3 herewith shows the impulse flashover of a string of five standard units and of a string of fourteen standard units for lightning surges of different steepnesses of wave front. The figures are approximate and subject to modification due to further knowledge obtained in the laboratory. We deduce from our laboratory investigations that any lightning wave whose crest reaches the 60-cycle value and exceeds it for a fraction of a microsecond will cause flashover of the insulator string.

The importance of impulse factor to various steepnesses of wave front lies in the fact that the surge potential from a lightning stroke would reach extremely high values if it were not for the flashover limit imposed by the insulator string itself. As a consequence, before the lightning surge has had time to reach anywhere near its crest value it is chopped, or discharged, by the flashover of the insulator string. It is interesting to note that even before the string has reached the flashover point, as indicated by the complete formation of the streamer along the length of the string, the conductivity over the string has increased enormously, so that the leakage current over the string, even before the actual flash takes place, is sufficient to reduce materially the potential of the surge before flashover occurs. When the insulator flashes over, the surge impedance at that point of the line is reduced to practically zero. Consequently, the remaining portion of the lightning surge is reduced to low potential and only the portion of the wave up to the flashover point passes over the line. This portion now is of relatively short duration as compared to the original lightning surge from which it is evolved, and may have a crest value several times the 60-cycle flashover of the insulator string. These chopped waves are of importance because they have this high crest value and may be a source of danger to the apparatus connected to the line.

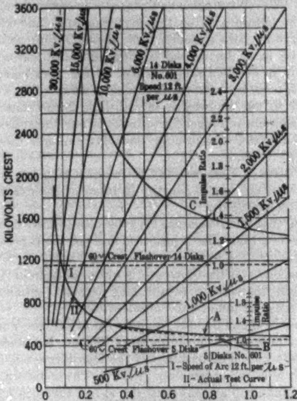

Fig. 3—Voltage Time Flashover Curves of Suspension Insulators

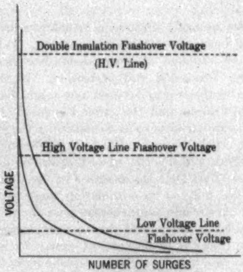
There seems to be a rather widespread misconception of the part played by the time lag of the insulator string in the operation of transmission lines. There seems to be an idea that high impulse factor increases the effective insulation of the line against lightning surges. Many recent tests indicate that any surge due to lightning which goes slightly over the 60-cycle flashover value of the insulator string will cause a flashover. If this be the case, the less the time lag, or the quicker the flashover, the less will be the severity of the surge impressed on connected apparatus. Furthermore, the time lag of an insulator string leads to an undesirable characteristic, namely, the tendency of a string of insulators to cascade. Fortunately, due to the fact that there is this large time lag in the flashover, we are able to make use of an auxiliary device, namely, the arcing ring, which when properly designed will, by improving the field of the insulator, increase the resistance of the string itself to the 60-cycle voltage, and consequently the tendency to flashover may be delegated to the arcing rings themselves which have probably a somewhat lower time lag than the insulator string. This can be done without sacrificing the 60-cycle flashover value of the string itself without the rings. In this way when flashover occurs the arc will form between the arcing rings and no cascading will take place over the string of insulators and as, in general, the power arc will follow the path of the impulse flashover, the use of arcing rings of proper design insures the insulator string against breakage due to cascading. The arcing ring, therefore, has two desirable characteristics: first, it prevents cascading of the string and, secondly, it tends to reduce the impulse factor for a given steepness of wave front. In other words, it gives to the insulator string flashover characteristics more nearly approaching that of spheres.

I should like to bring forward a broader point of view in considering the insulation of transmission lines. It is customary to consider the problem of transmission-line design in two aspects, namely insulation and protection. In the design of apparatus two methods may be used, one might be entitled the method of brute force, and the other the method of properly protecting the various parts so as to distribute the electric forces in the most favorable manner. We do not differentiate between these two methods and describe one as insulation and the other as protection. I feel that the progress in the design of transmission lines has suffered by considering these two aspects independently. As a result, controversies arise due to transmission engineers considering only one of these aspects instead of looking at the problem from the broad point of view. To illustrate this point, let us suppose we have a 220-kv. transmission line insulated with 14 units and we find that with these 14 units the number of outages per 100 miles per line amounts to a certain definite figure, and we wish to reduce this figure to some desirable value. There are two ways in which this may be done. We find that following the one way, which we will designate the method of brute force, we would require an insulator string with perhaps 28 units. This, of course, would mean that the towers would have to be raised at least 6½ ft., the necessary amount depending upon the design of the tower structure. This would in addition involve strengthening the tower to meet the increased stresses due to the added height. The second method would involve adding two ground wires in the proper position over the transmission line, the ground wires having at least one layer of good conducting material and being properly suspended so as to insure against mechanical breakage. Fig. 4 herewith shows that the effect of the ground wires as far as the outage is concerned, is the same as that due to doubling the length of the strings. This conclusion is based on an assumed reduction in the surge potential, due to the ground wire, of 50 per cent. This figure is believed to be conservative. Mr. Peek has obtained much higher values in laboratory tests. These higher values he ascribes to the formation of corona on the ground and transmission wires. However, we assume the conservative value until Mr. Peek's more optimistic values have been established by further tests.

We have here an example of two methods of achieving results desired, both of which will increase the construction cost of the transmission line. However, the advantages of the ground wires are not only due to the reduction of outages of a transmission line but are also due to the reduction of the surge potential and consequent reduction of hazard to apparatus connected to the line. If the first method is used it will be necessary to increase very substantially the insulation strength of the connected apparatus such as transformers, circuit breakers, transformer bushings, outlet bushings, etc., and, also, it would lead to an increased cost in the protective apparatus at the substation. However, a compromise can be made with the over-insulation method by using over-insulation only in the portions of the line exposed to lightning, using the lesser insulation at the unexposed points, but the reduction in outages will not be so great as if the extra insulation is used over the whole line or if ground wires are installed over the whole line. Another modification of these schemes might contemplate using extra insulation and ground wires in combination. For example, extra insulation might be used on portions of the line where grounding conditions aren't very good and ground wires may be used over other portions of the line where ground conditions are favorable and additional ground wires might be used in the neighborhood of the substation.

It will now be apparent that the insulation of the line, which includes so-called protective measures, is an economic problem, the problem of obtaining the lowest outage factor at the lowest cost. The two fundamental principles are the protective principle, such as the use of ground wires, and the principle of over-insulation. These two fundamental ideas can be combined in many different ways so as to obtain the best results. In the final result the effect on the substation apparatus such as transformers, circuit breakers, bushings, etc., must be considered. There are several other methods that are under consideration but have not reached the stage of development where they can be considered as being established. One of these methods is the use of arresters placed at intervals along the line. There is no doubt that if an effective arrester could be placed at each tower the result would be effective. Another method is known as the fused arcing ring. The economy and effectiveness of this method seems to rest almost entirely on the characteristic of the fuse. All these various methods can be considered properly as methods of effectively insulating the transmission line.



EFFECT OF GROUND WIRES

Fig. 4

There has been considerable controversy as to the advantage of using wood-pole construction and preserving the insulating characteristic of the wood pole itself. This of course comes under the heading of over-insulation. A great disadvantage of this method lies in the fact that the surges that are encountered in transmission lines are easily able to shatter, and from all accounts have frequently shattered the wood pole, leading to power outages due to mechanical failure. A modification of this method of obtaining improved insulation is the use of the insulated ground wire in conjunction with the wood pole. This has the advantage of preserving the wood-pole insulation and reducing the surge potentials to which the wood is exposed, thereby preventing a tendency to pole shattering. In the laboratory without lightning generator we are able to shatter wood poles of considerable length. It is easily seen, therefore, how much of a liability this pole shattering is in wood-pole construction where the line is exposed to lightning surge potentials and energies very much in excess of those that can be obtained in the laboratory.

Experience has shown that with certain types of line construction and degrees of insulation certain classes of transformer insulation are satisfactory and give good service. It seems to the writer that the method of classifying required insulation of connected apparatus by the number of units used in the adjacent insulator string is not only a good practical method of specifying the required class of insulation but is also scientific. In the future, the effect of the line construction on connected apparatus will be given more consideration and no doubt the use of special protective measures, such as additional ground wires near the substation, will grow in favor as more and more experience is obtained. The Westinghouse Company is carrying on investigations on lightning with the klydonograph, and expects to do further work with a modification of the Dufour oscillograph. It is hoped that, during the coming lightning season, by the above work in the field supplemented by the work being carried on in the laboratory with the lightning generator, we will materially add to our knowledge of lightning phenomena, thereby enabling us more intelligently to insulate our transmission lines against the effect of lightning, reducing outages due to this source.

**J. F. Peters:** I am heartily in favor of coordination of insulation but I am not so heartily in favor of the exact method suggested by Mr. Sporn.

In order that the insulation may be coordinated it will have to be done on a basis that is practical and not too expensive.

Insulation that goes into high-voltage apparatus, such as circuit breakers and transformers, is quite variable in its insulation strength; therefore, in establishing a chain of gradations this variation must be taken into consideration.

Referring to Chain 5 in Mr. Sporn's Table VII, you would have a line that must stand an impulse of 757 kv. but must fail at less than 834 kv. The bushings of the transformers must stand 834 kv. but must fail at less than 910 kv. The transformer windings must stand 910 kv. but must fail at less than 985 kv.

Now, the range between the values that insulation must stand and those at which it must fail are not large enough for practical application. It is one thing to design apparatus to withstand a certain voltage but it is an entirely different matter to design apparatus to fail at a point slightly higher than a specified value. By increasing those increments to a practicable value I am quite sure the strongest link in the chain will be so expensive that it cannot possibly be justified.

One way of getting around this difficulty that appeals to me as practical is to establish one point in the chain that is definitely weaker than the other links. That weak link logically should be either the line insulation adjacent to the station or some relief gap located adjacent to the station. When such a relief is fixed it would then only be necessary to say that all of the apparatus and substation insulation should be stronger than so much and in specifying this strength I heartily agree with Mr. Montsinger's suggestion of putting it in terms of 60-cycle dry flashover.

In connection with Mr. Lewis' paper, I have had occasion in the last few years to look over quite a few records of surge investigations on actual transmission systems and I have observed that there appear to be two kinds of impulses, one that comes under Class A as listed by Mr. Lewis in Fig. 3, the other as Class C in the same figure, and between these two types there seems to be quite a wide band. I do not have sufficient information to state why this wide band exists but I am inclined to believe that the Class A are due to direct line hits and Class C are due to induced strokes. Now if this is the case, can we draw the conclusions that ground wires will have the same effect on reducing Class A disturbances as they will for Class C? All of the theories concerning ground wires are based on induced strokes and cannot apply to the direct strokes in the same way. There is no doubt that the presence of ground wires will divert many of the direct strokes and in that way will materially protect the line against such disturbances. But will they divert all of the direct strokes? If not, then the installation of ground wires will not produce lightning-proof lines.

**F. W. Peek:** It is significant that in these papers and in the discussion, lightning is expressed in numerical values; it is on an engineering basis. It is now known that the maximum lightning voltage that can appear on a transmission line depends upon the height of the line above ground and whether or not a ground wire is used. The maximum voltage that reaches the station and the apparatus is the lightning breakdown voltage of the line or the lightning arc-over voltage of the insulators. Since the voltage to which the apparatus is subjected is thus determined by the line insulators it is readily seen that it is not logical to use apparatus with a lower lightning breakdown voltage than the line insulators in the vicinity of the station.

An examination of statistics shows that a very small fraction of 1 per cent of transformers is damaged each year by lightning. Thus present transformer insulation is fairly well matched with present average line insulation. It would thus not be economical to add greatly to transformer insulation as long as the present average line insulation is used. However, as better service is demanded it is necessary to over-insulate lines in parts of the country where lightning is severe. If this over-insulation is carried up to the station the transformer strength should be increased in proportion to the increase in the insulation on the line. In many cases it will probably be found that satisfactory operation will be obtained with average insulation in the vicinity of the station and with any desired over-insulation out on the line. The lower insulation near the station on a comparatively short section would usually not appreciably increase the outages. This follows because the chance of an arc-over on a short section is small and further because high lightning voltages are rapidly reduced by corona and other losses before traveling a very great distance on the line. I am quite in sympathy therefore with the suggestions for balanced insulation on lines and apparatus as suggested in the papers by Mr. Lewis and Mr. Sporn.

Mr. Lewis has tabulated the average number of line insulators for various operating voltages and suggests that if the line insulation is increased above the average the transformer insulation should be also increased proportionally. He suggests that this increase be measured by the usual 60-cycle test of the transformer and that the line insulators be expressed not in terms of the number of units used but rather in terms of the 60-cycle arc-over voltage of the insulators. This is quite rational and removes a number of difficulties as to the lightning wave shape used, etc. It so happens that if a line insulator will protect a given transformer by flashover for a given lightning wave it will also protect it for other lightning waves. All this means is that over a wide range of transients the ratio between the lightning breakdown voltage of the insulator and of the transformer remains more or less constant. This follows because the insulator is a time gap or requires time to cause arc-over. It thus automatically takes care of changes in wave shape.

Another advantage of the insulator as a practical means of measuring the lightning voltage of transformers is that the operating engineer knows immediately whether or not the number of insulators on his line is stronger than the transformer.

I do not mean, of course, in endorsing Mr. Lewis' suggestion of using insulators as a measure of lightning strength of transformers that the actual lightning strength for various wave shapes should not be measured in the laboratory. In fact, we have done this very thing.

The following tests are given as illustrations and have particular bearing on the present discussion. Transformers were set up in the laboratory and connected to a transmission line supported by the usual line insulators. Lightning waves from the 3,500,000-volt lightning generator were sent over the line and the strength of the transformers measured in terms of insulator disks as well as voltage. These tests have been made with a number of different types of waves. I am particularly interested in this discussion because in 1915 I presented a paper before the Institute—*The Effect of Transient Voltages on Dielectrics*—covering this subject. In that paper the term "impulse ratio" was first used, as well as the term "micro-second" as applied to time lag and insulation breakdown. In this early work it was not possible to take oscillographs. However, this is now being done in the laboratory and studies have been made on insulator flashovers and insulation strengths with waves varying in length from 1/25 micro-second to several hundred micro-seconds.

By full use of available knowledge, it appears that transmission lines can be made almost or practically lightning proof.

**K. K. Palueff:** To illustrate the great variation in lightning characteristics of existing transmission systems I prepared, some three years ago, a table given below and quoted in part by Mr. Lewis.

| Rated voltages | 66 | 88 | 100 | 110 | 120 | 132 | 220 |
|---|---|---|---|---|---|---|---|
| Total circuit miles...... | 4880 | 717 | 1617 | 2895 | 468 | 882 | 1150 |
| No. of suspension insulators—............... | | | | | | | |
| Minimum........... | 4 | 5 | 5 | 6 | 8 | 9 | |
| Maximum........... | 6 | 7 | 8 | 9 | 9 | 0 | |
| Average............ | 5 | 6 | 6.4 | 7.23 | 8.83 | 9.7 | 13. |
| Height of lowest conductor at the tower—..... | | | | | | | |
| Minimum........... | 22 | 28 | 34 | 25 | 30 | 42 | |
| Maximum........... | 53 | 47 | 55 | 68 | 61 | 55 | |
| Average............ | 35 | 38.5 | 38.7 | 47 | 57 | 46.7 | 55.6 |
| Percentage of total mileage that data are given on—............... | | | | | | | |
| Number of insulators. | 100 | 78 | 100 | 100 | 100 | 100 | 52 |
| Number of conductors | 75 | 100 | 86 | 83 | 100 | 100 | 52 |

Since this table was prepared, the writer has learned of a 66-kv. system having 9 disks on entire line, of a 110-kv. system having 10 disks on entire line, and 15 disks at the substation end, of 132-kv. system having in addition to 9 disks 7.5 ft. wooden crossarms.

It also was found that a great many systems, having a more or less normal number of disks, were using wooden poles and crossarms with ungrounded hardware, which in some cases more than doubled the actual dielectric strength of the line.

Since Mr. Peek's laboratory investigation showed that lightning voltages on transmission lines may often exceed their dielectric strength, it became obvious that line insulation should be used as a measuring stick of dielectric strength of varius apparatus connected to it.

However, study of the line insulation data given above indicates that if such a principle is accepted then transformers and circuit breakers on some systems must be capable of withstanding high-potential test equal to far more than twice line operating voltage. For instance, a transformer for a 66-kv. system, with 9 disks as mentioned above, would require a high-potential test of four times normal (264 kv.). This of course means a substantial increase in cost of the apparatus.

The experience of some operating companies has proved the correctness of this principle, and forced them to buy transformers capable of standing a high-potential test of more than twice operating line voltage for their "over-insulated" lines.

The second group, however, were inclined to attribute the cause of their operating troubles to defectiveness of the apparatus, which attitude deprived them of an opportunity to benefit by their experience.

The third class of engineers, being annoyed by arc-overs of the bushing on circuit breakers and transformers, realized that the dielectric strength of their apparatus was lower than that of the lines, but instead of following the example of the first group they established a habit of securing extra strong bushings matching with line insulation, leaving, however, the apparatus proper at the original strength, thus virtually making the most expensive part of the transmission system the weakest.

It is on account of the above consideration that I most heartily welcome the recommendation of Mr. Sporn's paper.

The important question is how to ascertain the lightning strength of the apparatus. Making an impulse test as part of the acceptance test is at present quite out of the question, for two reasons: first, the range of shapes, and the magnitude of characteristic traveling waves met with in service are not sufficiently well established; second, there is no way of determining the place and degree of partial damage that may be done by such a test to a transformer. It is quite possible to puncture insulation between adjacent turns or even coils, with so little energy concentrated at the point of failure that it would be absolutely impossible to find the latter even after complete disassembly of the transformer.

Transformers respond to impulse, not as a pure inductance, but as a very complicated network of distributed capacitances and inductances. The result of it is that high-frequency voltage may concentrate between adjacent turns or coils.

This phenomenon is excellently described in Messrs. L. F. Blume and A. Boyajian's paper on *Abnormal Voltage within Transformer Windings*, (TRANS. A. I. E. E., Vol. XXXVIII, Part I, 1919, p. 577).

Thus two transformers, equally strong at low frequency (not greatly in excess of 500 cycles), may have quite different lightning strength. In spite of that, however, it seems that the only practical method of making acceptance tests is to subject apparatus to a sine-wave voltage of low frequency (say between 25 and 500 cycles). The value of low-frequency arc-over of the line insulation (which must include wooden cross-arms in case hardware is not grounded) of the system under consideration should serve as a criterion for the magnitude of potential test of the transformer.

**J. F. Peters:** I should like to add a few comments to what Mr. Palueff has stated so as to prevent any possible misunderstanding of the discussion. He gave a very beautiful analytical discussion that applies to an abrupt application of voltage to a transformer winding. His conclusions are what would happen if there were no other factors present except the capacitance and inductance of the windings; but what actually happens in service is quite different. All high-voltage apparatus are equipped with bushings that have high enough capacitance to alter very considerably the internal state of affairs. With a typical high-voltage transformer, if an impulse with a sheer front is applied, the capacitance of the bushings will absorb this impulse to such an extent that it will increase gradually to its full value in something like five microseconds. That being the case, the voltage is applied to the windings slowly enough that it distributes quite uniformly throughout the winding.

**C. D. Gibbs:** (communicated after adjournment) The papers by Mr. Lewis and by Mr. Sporn represent the first serious consideration given to coordinating the insulation of transmission lines with that of equipment. It is a feature that most engineers have encountered, but which, due to lack of data, has largely been settled by guess.

One point which I wish to bring out is that the problem has been started on the premise that the lines must be insulated to prevent flashover during lightning storms. This premise is justified only on some of the higher capacity lines such as the 220-kv. trunk lines where an interruption involves a loss of a large block of generating capacity. On the usual transmission line a circuit can be dropped out of service without upsetting the operation of the system and in these cases there is no justification for the expenditure necessary to make the line lightning-proof.

Too much effort is being made to secure higher and higher flashovers for transmission lines. By the use of wood poles, arms, and braces, the flashover may be doubled but the use of the overhead ground wire reduces the potential which will cause flashover by 50 per cent, so the number of interruptions remains the same in each case. In the former, the terminal equipment will be subject to much greater stresses. The additional cost of the extra insulation at terminals and on the lines must be very carefully weighed against the value of the loss of a line. After the terminal equipment is already established, the line insulation should be such that it does not endanger the equipment. That is, the problem is reversed. Instead of the line insulation being fixed and the transformer insulation determined from it, the transformer insulation is fixed and the line insulation should be coordinated with it.

Mr. Lewis recommends flat spacing of conductors. Such a recommendation is not based on the economics of the case. It has been determined that for a given width of right-of-way, 50 per cent more power can be transmitted at 132 kv. than at 220 kv., by using the conventional two-circuit tower for the 132-kv. line. This value may be further increased by using a three-circuit tower having the conductors in the vertical plane.

Another recommendation is that the flashover of the last one-half mile of line be lower than the rest of the line and additional ground wires installed. It is not apparent why this last one-half mile should be designed to function as an arrester. To do this, additional tower designs will have to be made resulting in an increase in the number of types used on the line with consequent increase in cost. Towers and insulators are very poor arresters. They may be satisfactory in relieving the overvoltage but every flashover is attended by an interruption.

It appears that the arresters should be called upon to perform the functions which Mr. Lewis assigns to the insulators of the last one-half mile of line. If the arresters are of insufficient discharge capacity they should be designed larger. Larger choke coils may be of distinct advantage or the installation of arresters on the bus. In any case, the arresters should not be rendered useless by permitting flashovers that will drop the line out of service when it can be avoided without additional cost.

**C. A. Jordan:** (communicated after adjournment) Despite the general tone of optimism which pervades Mr. Lewis' paper, lightning flashovers have occurred, and probably will continue to occur, on the most strongly insulated lines in service today. Probably a greater percentage of high surges measured on transmission systems by surge-voltage recorders arise from direct strokes to line structures or conductors than is now generally realized. Especially for lines of moderate voltages, it is not to be expected that any amount of insulation or ground-wire protection, within practical limits, will prove effective against these.

By increasing insulation levels of important transmission circuits and installing additional ground wires, much may be done to increase immunity to the average run of severe induced surges; hardly, I believe, as much as Mr. Lewis anticipates, however. For some unexplained reason, the operating history of transmission circuits with ground wires, engineered in accordance with the best modern thought, has fallen short of the bogey set by Mr. Lewis' data. For the past two or three years, numerous and earnest efforts have been made to measure with klydonographs the shielding effect of ground wires on operating circuits, without finding voltage reductions of the order indicated in this paper. In fact, to my knowledge, no reliable records of any considerable reduction have been obtained to date. As the theory of the ground wire is generally understood, it must remain substantially at ground potential to exercise any appreciable shielding effect. Quite apparently, due to impedance in the ground wire and its earth connections, and possibly due to other factors of which we now have no knowledge, field conditions depart materially from laboratory conditions, even in the best of circumstances.

Since flashovers initiated by lightning cannot in the nature of things be avoided, it becomes necessary to exercise such control as is possible over the locations of these flashovers. It is not always easy to incorporate this control as a basic feature of design with confidence. The great difficulty is an almost utter ignorance of the surge impulse strengths, under various conditions, of the insulations commonly employed by the industry. I make this statement advisedly, having some slight knowledge of the research work which some manufacturers and operating companies have been, and are, conducting. Rational design will not be possible until the voltage-time characteristics and rates of fatigue of the common insulations, individually and in the combinations usually employed, have been determined, and the range of surge characteristics to be met with in practise has been established. The application of the cathode ray oscillograph bids fair to supply much of the latter information within the next few years. Laboratories equipped with surge generators should not lag in developing technique and determining the equally important insulation characteristics.

Only lightning discharges within a very limited area surrounding the yard can affect the substation directly. Thus the maximum fundamental value of most surges which can appear in the yard will be governed by the surge flashover voltage (which is variable within wide limits) of the insulators at the line entrance. If the yard and particularly the bus insulators are weaker than the entrance insulators for any surge condition, there is risk of yard flashover causing a station shutdown. If a flashover occurs on the oil circuit breaker bushings, there is usually the same risk. If a surge of dangerous magnitude penetrates the yard still further to the transformers before finding a point of relief, there is possibility of transformer failure. Obviously it is preferable to avoid yard flashover entirely, if possible.

It is because of the present lack of data upon which to base intelligent design, and the gradual realization of what must be done to improve the situation, that the self-protecting transformer has, of recent years, received serious consideration as a forward step in system design. The self-protecting transformer is one in which the internal insulation, taken as a whole, is able to support any potential which can pass the bushing. Granted, bushing failure is undesirable, but as between bushing failure and transformer failure, the former is the lesser of the two evils.

Mr. Lewis now proposes that the insulation strength of transformers to surge potentials be gaged in terms of the 60-cycle flashover voltage of the insulators used on the lines for at least one-half mile immediately adjacent to the station, and suggests limiting values of line insulation for the nominal system voltages 66 kv. and above. I do not believe this proposal, if generally adopted, will best promote the interests of the art. Aside from the obvious advantage of relieving the manufacturer from the development of improved methods of testing with a possible saving in production costs, no other advantage is, for the moment, apparent. On the other hand, the proposal has several serious disadvantages and even dangers.

The relative strengths of insulations vary materially with wave shape. Too little is at present known regarding distribution of surge stress throughout yards and apparatus in general, and transformers in particular, to feel any degree of confidence that all will be well if insulation strengths are graded for 60-cycles alone. Mr. Palueff in his discussion has analyzed this situation very well as regards the transformer.

The restriction of line insulation in a zone a half mile or more around a station has the serious operating disadvantage that it increases the likelihood of unnecessary line interruptions, even though ground wires be used, because advantage cannot be taken of surge attenuation in this zone. Such an extensive arrangement of "impulse spillways" does not seem necessary. A number of operating companies is using one set of protective gaps at the line entrance or elsewhere in their yards with satisfactory performance in limiting the magnitude of surges passing a point.

Modern high-voltage switchyards are usually quite extensive. A line entrance may be 1000 or more feet distant from a transformer bank. Limitation of line insulation at point of entrance would be of little benefit to the distant transformer bank. It is true that such a case is special and protective gaps or lightning arresters should be installed adjacent to transformers, the line insulation no longer being the governing factor. But the point is that a high percentage of installations *would* be special and the proposal to reduce insulation adjacent to the station could not be applied universally, even if it were desired to do so.

The greatest danger to progress would be a tendency, as a path of least resistance, to perpetuate the expression of one thing in terms of something entirely different, and related to it only in a very general and variable way. A sound eventual solution cannot be expected in that manner. The only cure is continued investigation and research. It will cost the industry effort and money, but I believe the expenditure will be more than justified.

**W. W. Lewis:** Referring to Mr. Peters' statement as to the effect of the capacitance of a high-voltage bushing in modifying an impulse which may reach the bushing from a transmission line:

I do not believe that a high-voltage bushing will have very much effect in this respect. This is apparent from the following consideration: An overhead transmission line has a capacitance to ground of the order of 0.010 $\mu$ f. per mi. The capacitance of a power transformer from high-voltage terminal to ground is of the order of 0.002 $\mu$ f. and a high-voltage bushing has a capacitance to ground of the order of 0.0002 $\mu$ f. Thus it will be seen that the capacitance of the transformer itself is 10 times that of the bushing and the latter has a capacitance that is equivalent to only 1/50th of a mile of line. In addition, the station busbars have an appreciable capacitance to ground, in some cases equal to or greater than that of the transformers.

Neither the transformer nor bushing capacitance would have any appreciable effect on a wave of very long duration. A short wave or a wave that had been chopped off by the line insulators would be affected slightly by the combined capacitance of the busbars, transformers, and bushings. The greater effect, however, would be due to the capacitance of the busbars and transformers. The bushings would have an insignificant effect, as they only add a few per cent to the station capacitance.

In considering these matters, we should take account not only of the most favorable cases, but also of the most severe cases. In these cases, we will not be able to lean very heavily on the station capacitance, which is too low to give much protection.

**Philip Sporn:** (communicated after adjournment) I was frankly very much disappointed and surprised at the stand taken by Messrs. Montsinger, Lloyd, Peek, and Peters in regard to the question of actually measuring impulse voltage. They stated it would be better to specify impulse strength in terms of insulators. Disregarding the point that Mr. Peek himself made, that it isn't until you begin to express data or relationships in actual numerical quantitites that you can claim that you are even beginning to talk in a scientific manner, I think there are numerous objections to expressing impulse strength in terms of insulators.

For one thing—and I believe this is the principal objection—there is great danger that by adopting that practise we will only continue the situation that we are confronted with now, which is admittedly bad. The operating people now find that they had been lulled into a false sense of security: they bought equipment that was apparently good for certain voltage and sat back satisfied but later found it was breaking down, and it wasn't breaking down at the voltages for which they bought it but at other voltages. If the equipment is able to stand up for those other voltages they might as well know what magnitude it can stand up to and then they can use their judgment in determining how much of a factor of safety they ought to have.

Another objection to the proposed method of measurement is the fact that when we do express insulation strength in terms of insulators it might get us in trouble under a situation where a wave below the flashover value, say of the bushing of the transformer, comes in and is reflected at the transformer itself.

There is still a further objection, particularly on low voltage where wood lines are used. That is, if you talk of transformers or other apparatus as being good for a certain number of insulators, there is danger it will be taken at its face value, and we are going to have the difficulty that we are confronted with today and which Mr. Palueff brought out, and that is that you might have five insulators on a wooden line but the equivalent insulation strength might be actually 12.

It seems to me several of these difficulties could be eliminated if we started to express these values as actual numbers.

The objection has been raised that we haven't a standard. Well, that is only another good argument for establishing one. Standards have been established with regard to other quantities and can be with regard to this.

I don't think that anybody is particularly anxious to get insulation values down to a point where they will be expressed in such values that the accuracy will be good to plus or minus one per cent, but even though we don't go to such precision it will be still better, I think, to express them in actual numbers.

I think Mr. Fortescue has brought out the fact that the impulse flashover on a wave where the peak isn't reached in less than a microsecond is the power frequency flashover value. That may be so. I don't think there is any agreement on that, and it only brings out a point I have made, that we are still groping blindly and will continue to do so until we get some actual oscillographs on a number of systems, on many systems, and get hundred of oscillograms and find out exactly what lightning is and what its limits are, and so forth.

Mr. Peters has stated that he believes that the conditions today are very good and that, in general, transformers are standing up well, and apparently there is really no reason for disturbing them. I find it difficult to agree with that point of view. You don't have to have ten per cent of your transformers or of your other equipment failing to be in real trouble. For a particular station which may be one out of fifty stations on a system, a failure once a year or once every five years is a very serious matter, and it may cause considerable damage.

Neither do I agree with Mr. Peters in his statement that, if the strengths that were proposed in Table VIII were spaced by a practical amount instead of roughly the ten per cent as was suggested, the link of highest installation would reach so high a value that it would be entirely impractical. I know that in our own company we have now for a period of eleven years on one particularly extensive system been buying transformers considerably over-insulated; in fact, the standard specified has been a three times normal test instead of twice normal—the present A. I. E. E. Standard. Quite regularly, generally once a year, we survey the results of previous years to see whether we want to continue the same policy for the following year or two, and so far we have found it a paying proposition to continue it. I know, too, that we found it necessary to go up to higher insulations than the Institute Standards on some of our other voltages, and I believe there is quite a number of other operating companies doing, or starting to do, the same thing today.

I do not think that the question of rationalizing insulation strength is a particularly easy one, and I certainly did not want to convey the impression that it is. But suppose it isn't. There is a lot of work to be done on it. But if you examine Figs. 1 and 4 in the paper, Fig. 1 showing the present status with regard to insulation and Fig. 4 the proposed arrangement and presumably the status that will exist if the idea with modifications is carried through, I think that there is a good chance that the conclusion will be that all the trouble that may be necessary to bring about the conditions shown on Fig. 4 will have been worth while.

# High-Speed Recorder

BY C. I. HALL[1]
Fellow, A. I. E. E.

***Synopsis.****—This paper describes a new electrical instrument for automatically recording variations of electrical functions at high speed. The rate of chart motion is lower than that of the oscillograph so that the envelope of an a-c. wave is produced. This recorder has been successfully applied in the analysis of breakdowns on transmission lines, giving data used as the basis of securing improved selective relay protection and for other problems involving automatic high-speed recording.*

## INTRODUCTION

THE rapid adoption of interconnection and the formation of complex power networks have made it increasingly difficult to provide adequate relay protection for these systems. The location and settings of selective relays must be such that overloaded or faulty lines are promptly isolated and cut off with a minimum of interference to the service continuity of the remainer of the system. The high-speed recorder is an instrument which has been designed particularly as an aid in the solution of these problems. It has been built in a variety of forms having either one or more recording elements and giving either maximum values only, or records having a time base. It is started automatically by the excessive current incident to the fault and begins to record in approximately 0.03 sec. In its four-element form, it gives simultaneous records of the neutral ground current and each phase-voltage, for a period of 10 sec. after the occurrence of the fault. This covers the life of the disturbance, since the faulty section is usually cut off in a few seconds by the protective relays.

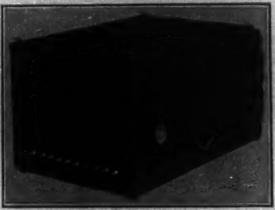


FIG. 1—GENERAL VIEW OF FOUR-ELEMENT RECORDER

Although the high-speed recorder was designed primarily as an aid in the study of line faults, it is obvious that it has numerous other applications, some of which are mentioned later. The recorder may be used in nearly any application in which automatic starting or high-speed recording are necessary.

The use of the recorder in analyzing transmission line faults has been described by E. M. Tingley in a paper entitled *The Hall High-Speed Recorder.*[2] Included in this paper were numerous records made in service on the system of the Commonwealth Edison Company. The purpose of the present paper is to deal particularly with the design and construction of the recorder, including sufficient test records to illustrate the varied application of the instrument.

## REQUIREMENTS OF RECORDER

The design of the recorder incorporates the following features, which are considered essential to a device of this class:

a. Automatic Operation: Recording is started by a high-speed relay actuated by increase in line current or other determining variable.

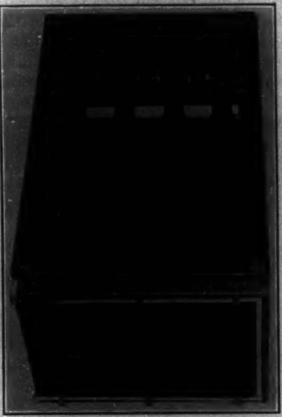

FIG. 2—INTERIOR OF FOUR-ELEMENT RECORDER

b. Speed of Recording: The record shows values for each half cycle on 25- and 60-cycle circuits.

c. Minimum Delay Before Beginning to Record: The total time after occurrence of the fault until the device begins to record is approximately 0.03 sec. It is

obvious that this lag must be short in order that no part of the record be lost.

d. Sturdy Construction: Comparable to portable ammeters and voltmeters. The instrument contains no delicate parts which are likely to become damaged with ordinary handling and care.

e. Portability: The recorder may be easily moved about from place to place, and set up in condition for recording.

Fig. 3—Auxiliary Relay for Four-Element Recorder

f. Improved Light Source: The light source is more effective and efficient than types used heretofore. An intensely brilliant point of light is produced on the recording film, yet the input is low, so that dry cells can be used as a power source.

g. Daylight Loading: Standard photographic film holders are used, enabling loading and unloading in daylight as with an ordinary camera.

Fig. 4—Record Made by Four-Element Recorder on System of Commonwealth Edison Company

## Classes of Recorders

As previously mentioned, the recorder has been produced in both four-element and single-element form. Views of the former device are shown in Figs. 1 and 2 while the latter is shown in Figs. 7 and 8.

Fig. 4 shows a chart obtained from a four-element recorder in service on the lines of the Commonwealth Edison Co. The upper record of this chart gives the variation in neutral ground current while the three lower records give voltage values on the three phases. Ordinates represent current and voltage values, and time movement is from left to right.

Fig. 10 gives a group of four calibration records made with a single-element recorder of the stationary film type. With this construction, maximum values only are recorded. The single-element recorder has been arranged also to give time-base records by the application of the moving film mechanism shown in Fig. 9. The latter is contained in a light-tight case which is attached to the top of the recorder proper, taking the place of the ordinary film holder shown in Fig. 7.

Fig. 5—Schematic Diagram of Light Source and Optical System, Four-Element Recorder. (Side View)

## Light Source

A side view of the four-element recorder drawn schematically is shown in Fig. 5. This cut also illustrates the type of light source used in all recorders. A small concentrated filament automobile type lamp, *A*, is placed in one end of a light-tight tube which also contains lenses *B* and *D* and a highly polished metallic hemispherical mirror *C*. The rays from the lamp are focused upon the hemispherical mirror, which, through reflected light, becomes a secondary light source of very small diameter and high intensity. The rays from this secondary source pass through lens *D* to the galvanometer mirror *E*, from which they are reflected to plane mirror *F* and thence are focused upon the record-

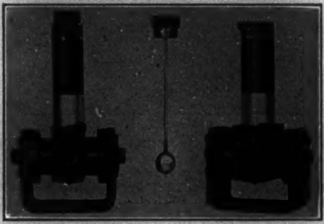

Fig. 6—Electrical Measuring Element. Front and Rear Views and Vane Only

ing film. During the time of recording, the plane mirror *F* is rotated at a definite rate in the direction indicated by the arrow by a governor-controlled spring motor. This rotation of mirror *F* causes the recording point of light to move across the stationary film at the rate of 1 in. per sec. Only one lamp and secondary source are required for all four recording elements, as four lenses *D*, located in an arc of a circle above *C* and transmitting light to four individual galvanometer mirrors are used. This will be understood by referring to Fig. 2.

Fig. 7—General View of Single-Element Recorder

### Electrical Element

A detailed view of a recording element is shown in Fig. 6. This element consists of a soft iron yoke supporting two adjustable poles which carry the winding. The moving element is a soft iron vane, mounted rigidly on the end of a stiff duralumin rod and set at an angle of 45 deg. to the flux path between the poles. An aluminum support riveted to the vane carries a galvanometer mirror and a guide bearing pivot. The vane and mirror assembly is shown between the front and rear views of the complete element. For use on a-c. circuits the electrical elements are connected to the lines through transformers contained within the recorder. In this way, proper ratings are obtained and a standard element can be used for recording either current or voltage. When d-c. circuits are being studied, the transformers are replaced by special external shunts.

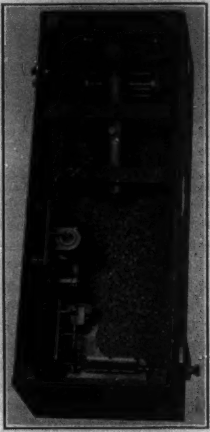

Fig. 8—Interior of Single-Element Recorder

The moving system or vane is of low inertia and high period of oscillation, so that it readily follows changes during each half cycle. In contradistinction to the usual indicating or recording element of standard instruments having a fine hair spring for furnishing the restraining torque, the elements of the high-speed recorder use the torsional force in the stiff duralumin rod mentioned above, to return the element to its zero position. The use of this relatively stiff moving system results in a very reliable element which is not liable to damage in shipment or handling. The light beams and photographic film used in recording also eliminate the inertia inherent in other methods of recording.

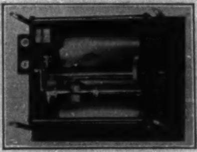

Fig. 9—Moving Film Mechanism for Single-Element Recorder

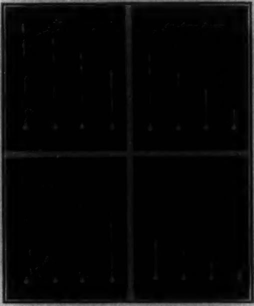

Fig. 10—Calibration Records Made With Single-Element Recorder

## OPERATION

As indicated earlier, the high-speed recorder begins operation automatically upon the occurrence of an overload, or fault. This is accomplished through a high-speed current-operated relay which is continuously connected in the neutral ground circuit. The high-speed relay for the four-element recorder is contained in a separate case (Fig. 3) while that for the single-element device is contained inside the case of the recorder proper.

In operating, the high-speed relay energizes three small contactors which connect the voltage elements to the line. The high-speed relay also turns on the recording lamp and releases a constant speed spring motor which rotates the plane mirror *F* of the four-element recorder or advances the film in the single-element recorder. At the end of the recording period a contact is opened by the spring motor which completely deenergizes the recorder control circuit, turning off the light source and disconnecting the recording elements. The operator, upon arrival, renews the film, rewinds the spring motor, and releases a latch in the high-speed relay. The recorder is then ready for operation again, and the exposed film is taken into a dark room for development.

## RECORDS

The size of record furnished by the four-element recorder is 11 in. by 14-in., and is made on standard film. The records made by the single-element recorder, stationary film type, are 3¼ in. by 4¼ in. and are also made on standard film. The single-element recorder for moving film uses standard 3¼ in. by 5½ in., 12-exposure Kodak film.

## SCALES

Standard deflection scales are as follows:

a. Four-element device
    70 volts per in.
    5 amperes per in.
b. Single element (ammeter)
    On 30 ampere coil —10 amperes per in.
    On 60 ampere coil*—20 amperes per in.

## TIME LAG OF RELAY AND LAMP

It is important that the time required for the high-speed relay to operate and for the lamp filament to reach recording brilliancy be very short, in order that the record may cover the complete disturbance. Tests have shown these time lags to be as follows:

a. Lag of High-Speed Relay on 60 Cycles

| Per cent of critical current | Time in sec. | Cycles at 60 ~ |
|---|---|---|
| 150 | 0.0058 | 0.348 |
| 200 | 0.0035 | 0.210 |
| 500 | 0.0020 | 0.120 |
| 1000 | 0.0012 | 0.072 |
| 2000 | 0.0010 | 0.060 |

b. Lag of Recording Lamp

| Lamp rating | Volts applied | Time in sec. for lamp to begin to record | Cycles at 60 ~ |
|---|---|---|---|
| 18-24 v., 27 cp. auto headlight. | 35.5 | 0.027 | 1.62 |

c. Total Time to Begin to Record
(Sum of lags of high-speed relay and lamp)

| Per cent of critical current | Time in sec. | Cycles at 60 ~ |
|---|---|---|
| 150 | 0.033 | 1.97 |
| 200 | 0.031 | 1.83 |
| 500 | 0.029 | 1.74 |
| 1000 | 0.028 | 1.69 |
| 2000 | 0.028 | 1.68 |

## MISCELLANEOUS APPLICATIONS

The possible applications of this type of instrument are numerous and varied. Figs. 11 and 12 show test records made using slight modifications of the standard recorder in order to give a time scale of 5 in. per sec. and also to add a timing indication to the chart. The latter was done by focusing the rays of a small high-speed filament hydrogen-filled lamp on the lower edge of the film. This lamp was operated by a 60-cycle supply circuit and thus produced on the record a row of timing dots 1/120 sec. apart.

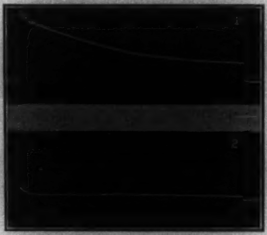

FIG. 11

1. 20-Ampere load applied to 1-kw., 150 volt, d-c. motor-generator set.
2. Starting current of 200-watt Mazda C lamp.

Chart 1, Fig. 11 shows the variation in current following the application of a 20-ampere load to a 150-volt d-c. line supplied by a small 1-kw. motor-generator set. The record shows how the current rose at once to a maximum value and then tapered down gradually, owing to a reduction in speed of the overloaded motor-generator. The detail of the record is exemplified by the small variations in the record line caused by sparking of brushes. The timing dots show that the complete interval during which the circuit was closed was 1.2 sec.

---

*NOTE. The ammeter coil of the single-element recorder is equipped with taps so that if desired, only one-half of the winding may be used, thus doubling the current capacity of the instrument.

Chart 2, Fig. 11 shows the starting current of a 200-watt Mazda C lamp, indicating the initial rush of current with cold filament and the reduction in value as the filament becomes heated.

Fig. 12 shows the blowing of plug and cartridge fuses under various conditions on a 220-volt d-c. circuit. In each chart, ordinates represent current values and time reads from left to right. Chart 1 was made by a 6-ampere plug fuse connected in series with a 20-ampere resistance load. The fuse blew in approximately 0.75 sec. and the arc was extinguished quickly. Chart 2 was made by another plug fuse of the same rating and with the same current value, but using an inductive rather than a resistance load. It will be noted that in this case the current value builds up more gradually and that an arc continues for about 0.35 sec. after the fuse wire has melted.

Fig. 12—Blowing of Fuses on 220-Volt D-c. Circuit

1. 6-Ampere plug fuse on 20-ampere resistance load
2. Same as "1" except inductive load
3. 5-Ampere cartridge fuse on 20-ampere resistance load
4. Same as "3" except inductive load

Chart 3, Fig. 12 shows the blowing of a 5-ampere cartridge fuse on a 20-ampere resistance load. Chart 4 shows the same conditions except for the substitution of an inductive load. It will be noted that the cartridge fuse opened the inductive current without the formation of an arc.

Other suggested uses for the high-speed recorder include the investigation of starting currents of motors, motor current values on high overloads of short duration, brief reductions in line voltage due to starting of motors or other high-current loads, and general laboratory investigations where the device may be used for visual readings or permanent records.

## Discussion

### HALL HIGH-SPEED RECORDER

(Hall)

### PAGES FROM THE HALL HIGH-SPEED RECORDER[1]

(Tingley)

New Haven, Conn., May 9, 1928

**Alexander Dovjikov:** In an effort to overcome the slow response of ink-recording instruments, Mr. Hall devised the instrument described in his paper and in the paper by Mr. Tingley. This instrument is of the type intermediate between the ink-recorder and the oscillograph. By introducing the galvanometer and photographic method of recording, Mr. Hall eliminated to a certain degree the distorting features of the moving masses of the recorder although a small amount of overshooting may still be observed on the records.

The convenience of the Hall recorder in using the stationary plate instead of a rotating film as in the oscillograph is compensated by the fact that the former cannot record a second disturbance until the photographic plate is changed. Due to this limitation the instrument will require more attention and in certain cases the operation of the system, such as the reclosing of a breaker on a fault, cannot be recorded unless the time of a single operation of the recorder is unreasonably extended.

The statement of Mr. Tingley that "starting on neutral ground current is the best compromise that can be effected" may be true in application to Mr. Tingley's system for measuring of values he had in mind but is not generally true for all systems because this relay, functioning on ground current, will not operate in case of a phase-to-phase short circuit unless it develops into a fault to ground. We believe that a modified negative-sequence relay, which may be applied to grounded or ungrounded systems and will operate in the case of a ground fault as well as in the case of a phase-to-phase short, will be preferable in many cases.

**C. I. Hall:** Mr. Dovjikov mentions the moving masses of the recorder, as affecting the accuracy of the instrument. It should be understood that the recorder element has been so designed as to have a minimum of inertia and high restraining torque in the torsional rod carrying the vane. The angular twist of the recording vane is very small (about 1.2 deg. per in. of deflection on the film). In addition, the optical method of recording eliminates all inertia effects other than those originating in the galvanometer element. As the result of the foregoing features of design, overshooting of the recording element is small and is not sufficient to interfere with the commercial accuracy of the instrument.

The comment has also been made that the stationary film used in the recorder permits of recording only one disturbance without renewing the film. This is true of the four-element recorder only, as the single-element device is equipped with an automatic moving film mechanism which records four successive disturbances.

# A High-Speed Graphic Voltmeter
# for Recording Magnitude and Duration of System Disturbances

BY A. F. HAMDI[1] and H. D. BRALEY[1]
Member, A. I. E. E. Associate, A. I. E. E.

***Synopsis.**—This paper deals with a graphic voltmeter for recording the magnitude and duration of system disturbances. It also deals with operating experiences with this device, together with the importance of the data obtained.*

---

### INTRODUCTION

THE high-speed recording voltmeter described in this paper is one of a number of types now on the market which have been built in order to supply the needs for a type of instrument which would give an accurate record of system disturbances. It was felt that such instruments would be useful in determining actual magnitude and duration of disturbances and their relation to the operation of high-tension circuit breakers and relays on apparatus connected to the system.

The first part of this paper deals with the description of the electrical and mechanical details of this instrument, with particular reference to the requirements which were submitted to the manufacturers who developed the device. These requirements resulted from four years of operating experience with a similar type of instrument which accomplished the results desired. The second part of the paper deals with the interpretation of the records obtained and their value to the engineering and operating departments in analyzing system disturbances.

Several years ago the Engineering Department and Test Department of the New York Edison Company investigated the methods available for obtaining records of voltage dips during disturbances on power systems, and as a result an instrument was developed which consists of a high-grade graphic voltmeter driving a chart at normal speed and an auxiliary circular chart driven at relatively high speed. To the pen arm of the graphic voltmeter is attached a long pointer in addition to the standard pen of the instrument. This long pointer reaches over to a circular smoked chart which revolves at the rate of 2.5 rev. per min. (24 sec. per revolution). This circular chart is driven by a d-c. motor operating from the station control battery so that its speed is not influenced by the changes in system voltage. With this device it is possible to obtain records of both magnitude and duration of all disturbances. Two of these instruments have been in successful operation for four years and have given quite satisfactory results. The main objection to this device is that the smoked chart has to be renewed after each disturbance. It was therefore desired to obtain an instrument which would eliminate the above difficulty by giving the high-speed record on the standard strip chart.

From the operating experience obtained with the above instruments, certain specifications were drawn which were placed in the hands of instrument manufacturers and resulted in the development of the instrument described in this paper. With this device the high chart speed is 3600 times the normal chart speed and the change-over is accomplished in 0.05 sec. or less (1 to 3 cycles for 60-cycle systems).

The following characteristics were required:

1. A graphic voltmeter responsive to all voltage fluctuations, but well damped so as to be free from over- or under-shooting even for 100 per cent voltage fluctuations (suddenly energized to 115 volts or 115 volts suddenly interrupted).
2. Instrument to take 1.0 sec. or less to reach 115 volts when suddenly energized.
3. High-speed timing accuracy to be within 0.1 sec.
4. Chart acceleration time 3 cycles or less on 60-cycle systems (0.05 sec.).
5. Low-voltage relay capable of being set to function on a voltage dip of 5 per cent of normal or less.

FIG. 1—GENERAL VIEW OF A GRAPHIC SYSTEM—DISTURBANCE RECORDER

The manufacturers were left entirely free to work out all details.

### DESCRIPTION

The device described in this paper is illustrated in Fig. 1. It consists primarily of a standard type of graphic voltmeter *A*, a chart accelerator *B*, a contact-making voltmeter *C*, and the necessary resistors *D* and *E*. The wiring diagram of this device, together with

---

[1] Assistant Engineer, The New York Edison Company, New York, N. Y.

*Presented at the Regional Meeting of the A. I. E. E., Northeastern Dist. No. 1, New Haven, Conn., May 9-12, 1928.*

28-59

the schematic layout of the component parts, are shown in Fig. 2.

All the component parts of the above device are designed to operate at 115 volts, 60 cycles, with the exception of the magnetic clutch, which operates at 120 volts d-c. The contact-making voltmeter can be set to function at all dips in voltage amounting to two per cent of normal, or more. Actually, however, it is set to function at 5 per cent dips.

Under normal operating conditions the strip chart of the graphic voltmeter *A* runs at the normal speed of 3 in. per hr.; the salient-pole induction motor of the accelerator *B* runs continuously at synchronous speed; and the contact-making voltmeter *C* being energized at full voltage holds open its contact *V*. As soon as a dip in voltage occurs, amounting to five per cent of normal or more, the contact-making voltmeter closes its contact and energizes the magnetic clutch of the chart accelerator *B*. When the clutch engages, the chart accelerator motor runs the strip chart of the graphic voltmeter at the high speed of 3 in. per sec. The high speed continues even after the disturbance is over, for a length of chart equivalent to 24 hr., or 24 sec. in actual time. At the end of this time, a cam, which is operated by a worm gear, located on the magnetic clutch shaft, opens the circuit of the magnetic clutch at point *X* (see Figs. 1 and 2). If the voltage is back to normal, the slow chart speed is resumed as the contact-making voltmeter contact *V* would then be open. In case the voltage is still below normal, the contact-making voltmeter will have its contact *V* closed and the cam will keep the device running at high speed for an additional period of 24 sec. Normally the cam holds the contact at *X* open.

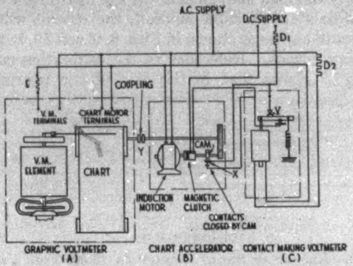

FIG. 2—SCHEMATIC LAYOUT AND WIRING DIAGRAM

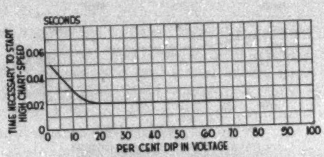

FIG. 3—STARTING TIME OF HIGH CHART SPEED

The time necessary for the accelerator to speed up the chart has been carefully investigated and was found to be dependent upon the magnitude of the voltage dips which affect the speed of operation of the contact-making voltmeter. For all dips amounting to more than 20 per cent of normal the device requires 0.02 sec., (1.2 cycles) to change over to the high speed. With dips less than 20 per cent, the change-over time may be as high as 0.05 sec. (3 cycles). The variation in this time is shown in Fig. 3.

The timing accuracy of the high-speed chart is correct within 0.1 sec. for the full length of the high speed run (72 in. length of chart) providing the dip does not exceed 50 per cent of normal. For greater dips in voltage, the accelerator motor slips and the timing error becomes greater. The curve in Fig. 4 shows the timing error during 24 sec. for voltage dips up to 70 per cent. For voltage dips beyond 70 per cent the driving motor stops if the disturbance is sustained. However, the motor requires about 5.5 sec. to come to rest even if the voltage fails completely. Fig. 5 shows the record of a 100 per cent dip lasting for 1.08 sec., where the magnitude was correctly recorded. The time was in error by 0.2 sec. It should be noted, however, that for 100 per cent dips lasting for more than one sec. the magnitude can be obtained directly from the chart even though the duration is not correctly recorded.

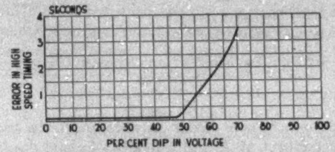

FIG. 4—TIMING ERROR IN 24 SEC. AT HIGH CHART SPEED

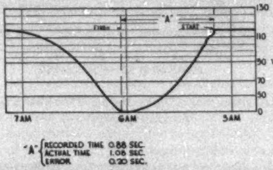

FIG. 5—TEST RECORD OF A COMPLETE VOLTAGE FAILURE

Voltage reestablished at the end of 1.08 sec.

To permit correct time resetting for slow speed after a disturbance, the high speed should last 24 sec., but actually it lasts only for about 23.96 sec. Therefore, there is a reset error in timing amounting to approximately 0.12 in. of chart length, which at slow speed means 2.5 min.

After the contact-making voltmeter operates to energize the magnetic clutch, 0.28 sec. is required for the cam to close the "hold-in" contact at *X* (see Fig. 2). Therefore, for disturbances having durations of less than 0.28 sec., the high speed lasts only as long as the disturbance, and the cam does not come into play. Fig. 6 shows such a short duration disturbance which was cleared in about 0.1 sec. However, if a number of short disturbances occur in succession, the cam will close the contact at *X* and a length of chart equivalent to 24 hr. will be run off as soon as the several short duration disturbances add up to 0.28 sec.

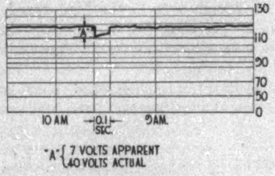

Fig. 6—Record of Momentary System Ground—Cause Unknown

In Fig. 7 is shown a set of calibration curves applying to this recorder. These curves have been prepared by subjecting the device to voltage dips of known magnitude and duration, and plotting voltage values obtained from the chart (ordinates) against time (abscissas). Normal voltage was 115 volts.

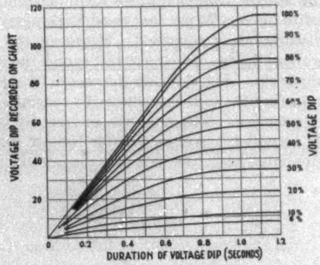

Fig. 7—Calibration Curves for Determining True Voltage Dip

The following procedure would be used to obtain the magnitude of a disturbance of known duration. From the high-speed section of the chart, obtain the apparent maximum dip in voltage and the duration of the disturbance. Plot the point corresponding to these two observations on the calibration curves. The true per cent voltage dip can then be obtained by comparing the position of the point so plotted to the calibration curves. As an example, if the apparent voltage dip were 40 volts, and the duration of the disturbance were 0.40 sec., we find by reference to Fig. 7 that the point determined by these two values falls very close to the 60 per cent dip curve. Therefore, we conclude that the actual dip was approximately 60 per cent of normal or 70 volts.

In connection with these calibration curves it should be pointed out that it is quite essential to have a properly damped instrument. If the instrument overshoots to a considerable amount, the records will not be smooth curves as shown in Figs. 8, 9, and 10, but will be wavy curves. Reference to the calibration curves in Fig. 7 shows that in the case of the instrument discussed, there is no overshooting and the instrument reaches full indication in about 1.1 sec. In other words, for disturbances lasting over 1.1 sec. there is no need for reference to the calibration curves, as the maximum dip recorded on the strip chart is the true dip.

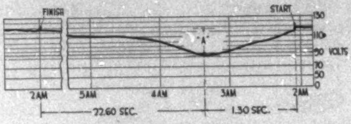

Fig. 8—Record of Short Circuit on 13,800-Volt Feeder

## OPERATING EXPERIENCE

Since this instrument was placed in service, on a 60-cycle cable system, 15 records of voltage disturbances were obtained. Most of these voltage dips were 20 per cent or less of normal voltage and the trouble was cleared from the system automatically in 1.5 sec. or less. While practically all of these faults show the same characteristics, there were a few cases of rather different nature which illustrate the adaptability of the instrument for this service. In the following figures the smooth voltage recovery sections have been cut off in order to shorten the length of the records. The broken lines show where chart sections have been cut off.

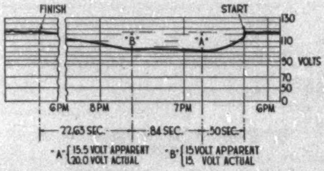

Fig. 9—Record of Short Circuit on 13,800-Volt Feeder

Fig. 8 is a typical record which is representative of the voltage disturbances resulting from faults on the system. This record shows a dip of 31 volts, or approximately 26 per cent, the disturbance being cleared by the opening of the circuit breakers after 1.3 sec. It may be noted that the duration of the disturbance is measured from the start to a point where the voltage begins to recover.

Fig. 9 illustrates a disturbance which lasted for 1.34 sec. before it was finally cleared. The first circuit breaker opened after 0.50 sec., while after an additional 0.84 sec. the second circuit breaker cleared the other end of the feeder. Since the first switch opened after but 0.5 sec. the instrument did not attain its maximum swing, the calibration curves showing the actual dip to be 20 volts instead of 15.5 as recorded. This curve also illustrates the manner in which it is often possible to obtain a check on relay operations, as two distinct circuit breaker operations are indicated.

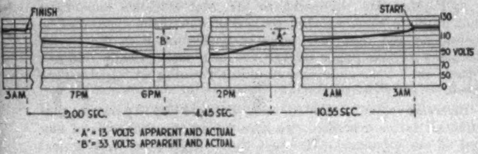

Fig. 10—Record of Ground and Short Circuit on 27,000-Volt Feeder

Fig. 10 is an unusual case in that the disturbance lasted for approximately 15 sec. before it was finally cleared. In this case a triplex cable became grounded at a considerable distance from the supply end and was not cleared immediately because the moderate ground current was insufficient to cause the overload relays to operate. The voltage dip due to the ground was approximately 11 per cent and lasted about 10.55 sec. Apparently the ground then developed into phase trouble causing a dip of about 28 per cent and was finally cleared after an additional 4.45 sec.

In each of the above cases the records show that a considerable length of time is required for the voltage to return to normal. Of this time, one sec. is due to time lag in the instrument if the dip is 100 per cent. If the dip is less than 100 per cent, the time lag of the instrument will be correspondingly reduced.

Fig. 6 illustrates a case in which a momentary ground occurred which apparently cleared itself in about 0.1 sec. The contact of the contact-making voltmeter opened before the cam could operate the hold-in contact to continue the high-speed operation.

While an instrument of this nature will not record instantaneous changes in voltage or current, it does afford a means of giving directly a fairly accurate picture of the disturbance even though it may last several minutes. All disturbances are recorded by this instrument even if they last more than 24 sec. because the instrument will operate continuously through successive periods of 24 sec. as long as the contact-making voltmeter contact is closed. An instrument designed to operate on current instead of voltage, for example, would give a record of surging between generating stations due to a condition of instability which might last for several minutes. Such an instrument may also be installed at grounding points to indicate the magnitude and duration of ground fault currents as a check on the effectiveness of the grounding itself and for checking relay operations.

The results obtained with the device described have been quite satisfactory from both the operating and the maintenance standpoints. The records obtained have given sufficiently accurate information in regard to the magnitude of voltage dips and their relation to operation of low-voltage relays. These records have an additional value in that they often afford a means of checking automatic circuit breaker operations and also give a fairly accurate indication of the effect of faults on the system in general.

---

## Discussion

**J. E. McCormack:** (communicated after adjournment) We have had some experience with an instrument similar in construction to the one described by Messrs. Hamdi and Braley in their paper.

We have experienced considerable difficulty in maintaining an accurate calibration on this instrument. The graphic voltmeter is equipped with an oil dash pot to damp the meter and prevent overswinging on a dip. The calibration of the meter depends almost entirely on the amount and viscosity of the oil in the damping chamber, and changes in temperature, or evaporation or leakage of the oil, will throw the calibration off.

We have also found that the slip of the induction motor driving the high-speed device is sufficient to cause a discrepancy in time as high as fifteen or twenty minutes on each high-speed run. This discrepancy varies with the amount and duration of the dip in voltage.

In respect to the electrical location of the disturbance recorder in the station, we have found that the only satisfactory method of connection is on one phase of one feeder or bus section. An attempt was made to connect a recorder to six 13,200-volt feeders on two sections of a bus, but the voltage difference between the two sections was sufficient to keep the chart running continually at high speed. Any method of connection to one feeder or bus with automatic throw-over to the other when the first is taken out of service is inherently wrong since the throw-over switch causes an indication of a dip at every operation. Also, a heavy dip is likely to cause the throwover relay to operate and makes an analysis of the dip impossible.

**D. J. Angus:** (communicated after adjournment) The desirability of speeding up the chart of graphic meters when important records are to be obtained was recognized about fifteen years ago, when the company with which the writer is connected was called upon to furnish graphic recording pressure gages for use in air-brake testing. These gages were provided with a pressure-controlled mechanism which speeded the chart up from three in. per hour to three in. per minute when any abnormal operation took place, and returned the speed to three in. per hour after this condition had passed.

Later, when public utilities felt the need for an instrument of this kind, it was found necessary to continue the rapid speed of the chart after the trouble ceased, until the chart came to the same time marking, 24 hours later on the chart, before resuming the slow chart speed, in order that a number of records could be secured in succession, without any attention on the part of the operator. Mr. Hamdi mentioned the cam-operated holding-in device, which requires approximately 0.28 seconds before it becomes operative. My experience has been that the holding-in device must operate the instant the high-speed drive comes into play, because if it does not, the circuit to which the tripping mechanism is connected may be disconnected by the automatic oil switches or other protective devices, and no high-speed records secured of the trouble and the recovery after the disturbance. Often this recovery will take several minutes, and a complete record of it is of utmost importance.

Instruments which the writer has designed for power-plant service are equipped with a double cam arrangement such that the first momentary impulse locks it in the high-speed position, where it remains until at least 24 hr. of chart (24 sec.) has been passed.

In the next to the last paragraph of Mr. Hamdi's paper, he mentions that an instrument designed to operate on current instead of voltage would give a record of surging between generating stations due to a condition of instability which might last for several minutes. We have actual records from large generating stations connected by tie lines operating out of synchronism for over four minutes, and numerous records where the system did not steady down to normal operation until after a minute had elapsed.

In addition to recording voltage and current in times of trouble, instruments equipped with the high-speed chart mechanism have for a number of years been used to record the power factor or phase position of the current in reference to the voltage in the generator leads and tie lines, the power transfer in kilowatts, kv-a. pressures surges in pipe line feeding hydraulic turbines, speed changes in prime movers, and pressure or other mechanical records of the functioning of governing equipment.

High-speed graphic recording instruments are long past the experimental stage, and hundreds of them are in use securing a wide variety of data on the operation of the various pieces of equipment that make up a modern power generating and distributing system.

**A. F. Hamdi:** Referring to Mr. McCormack's remarks, I should like to point out that we had predicted the difficulties he mentioned and that they have been eliminated in the device discussed in this paper by the use of a magnetically damped "dead-beat" voltmeter and a motor running at synchronous speed.

Referring to Mr. Angus' remarks, I should like to point out that with the device described, we obtain high-speed records of any and all disturbances. The fact that disturbances lasting less than 0.28 sec. do not result in a complete 24-hour run at high speed is of no particular importance, because usually such disturbances are of no serious consequence and they clear themselves as discussed in connection with Fig. 6 of the paper.

Particularly in view of the facts brought out by Mr. McCormack, I have to take exception to Mr. Angus' statement and hold the view that although hundreds of such devices are in use, they are still more or less in the experimental stage.

# Selection of Motor Equipment by Principle of
## Similar Speed-Time Curves

BY BERNDT A. WIDELL, JR.[1]

Member, A. I. E. E.

***Synopsis.**—Data for making preliminary estimates of speed of cars required and capacity of motor to do a given service have been rather limited. The object of this paper is to show a method whereby it is possible to provide curves which are simple to calculate and easy to apply.*

*No mathematical formula has ever been derived to express the speed-time or current-time curves for a railway motor. Similarity between speed-time curves has been resorted to and this paper shows how this method can be used to give very accurate results by proper consideration of the various factors which influence the shape of the speed-time curve.*

*Previous methods for estimating motor capacities are based on the horsepower of motor required, but with the advent of the self-ventilated and blown motors it is necessary to calculate the r. m. s. current for a given cycle and select a motor having this continuous rating. A method for doing this is proposed, based on similar current-time curves.*

*The limiting values of average running speeds for given rates of acceleration and braking, and the data for obtaining motor capacity necessary at these limits are indicated on each curve. This helps one to visualize why it is not practicable to perform certain schedules on a fixed rate of acceleration and braking basis.*

ONE of the most complicated engineering problems is that of selecting the proper motor equipment to perform a given railway service. By "service" we mean that cars must make a given number of stops and slowdowns over a route in a given time. In many instances the profile of the route is hilly, and voltage varies on different sections of the route, thus making it necessary to consider small sections of road at a time in our calculations to arrive at a suitable motor equipment. Unless one has had considerable experience in the application of motors to different services, it may require weeks of calculation to determine on the motor equipment of required speed to do the service with the least energy consumption and a conservative motor capacity. As a first approximation it is usually assumed that the route is absolutely level. An average line voltage is also assumed, thereby reducing the work to a few simple speed-time curves. In the majority of cases, such a solution is accurate enough, but if it is not, sufficient information has been obtained to shorten the work of making detailed calculations over the entire profile as it actually exists and for the varying line voltages. Even with this simplification, considerable calculation may be necessary before the proper speed equipment is determined, or it is found that an uneconomical or impossible schedule has been requested.

Several electric railway engineers (among them, E. H. Anderson, A. H. Armstrong, and F. W. Carter) have plotted curves from which a rough approximation of the speed of equipment necessary to do a certain service can be made. These curves have been prepared for a very limited group of conditions for which they give accurate data. They can also be used, however, as a rough approximation for other conditions, but realizing that much more accurate curves could be plotted to cover greater ground, an investigation was made which showed that the car friction and slope of the motor speed-tractive effort curve were the factors which most influenced the shape of the speed-time curve, and hence the schedule speed, for a given rate of braking and acceleration. Referring to Fig. 1, curves *B* and *C* are speed-time curves for a certain weight of car, making the same scheduled speed for the same length of run. The speed on leaving control and free running speed are shown in the table. It should be noted that for the same value of car friction there is a 5.5 per cent difference between speeds on leaving control, and 7 per cent difference between free running speeds, due to different motor characteristics alone. Comparing curve *C* with *A*, the difference between speeds on leaving control and free running speeds is 15 per cent and 19 per cent respectively. Obviously, if we are to make up curves that are to possess any degree of accuracy, the car friction and slope of speed—tractive effort curve must be considered.

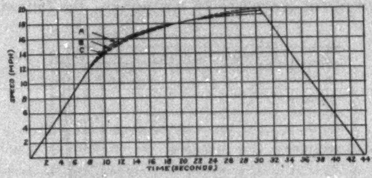

FIG. 1—SPEED—TIME CURVES ILLUSTRATING THE DIFFERENCES IN SHAPE DUE TO THE SLOPE OF SPEED TRACTIVE EFFORT CURVE AND THE CAR FRICTION

A—Average motor characteristic, friction 40 lb. per ton
B—Flat motor characteristic, friction 20 lb. per ton
C—Steep motor characteristic, friction 20 lb. per ton
Speed on leaving control (mi. per hr.) A—12.9, B—11.8, C—11.2
Free running speed (mi. per hr.) A—20.1, B—22.3, C—23.9

Conditions: Length of run 830 ft., rate of acceleration and braking 1.5 mi. per hr. per sec. Average running speed 12.96 mi. per hr. Constant car friction

First let us consider the effect of the slope of motor

[1] Of the Motor Division, Ry. Equip. Engg. Dept., General Electric Company, Erie, Pa.

*Presented at the Northeastern District Meeting of the A. I. E. E., New Haven, Conn., May 9-12, 1928.*

characteristic on the schedule speed. In order to distinguish between two different motor characteristics, the one whose speed tractive effort curve has the greatest slope is termed steep, whereas that with the less slope is flat. Fig. 2 illustrates the difference in the two motors' characteristics. Referring to Fig. 3 and assuming the number of stops per mile being made as one, we can read the free running speed corresponding to the average running speed directly. With an equipment geared to 75 mi. per hr., the following average running speeds can be made with a motor having the steepest and flattest characteristic respectively 34.6 mi. per hr. and 35.3 mi. per hr., a difference of 2 per cent. With a 35-mi. per hr. equipment, the difference in average running speed is 1 per cent, and with an equipment of 30 mi. per hr., an average running speed of 24 mi. per hr. is obtained with either slope of characteristic. Over the usable part of this curve, the maximum variation in average running speed due to the slope of motor characteristic is 2 per cent. If we base the curves on an average motor characteristic as indicated, the maximum variation in average running speed from either steep or flat characteristic is about 1.4 per cent.

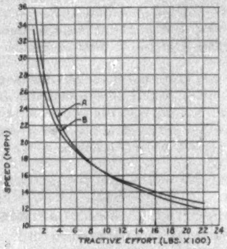

FIG. 2—SPEED—TRACTIVE EFFORT CURVE OF TWO MOTORS HAVING A DIFFERENCE IN SLOPE

A—Steep motor characteristic
B—Flat motor characteristic

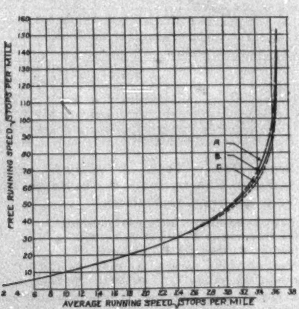

FIG. 3—CURVES ILLUSTRATING THE DIFFERENT FREE RUNNING SPEEDS REQUIRED FOR MOTORS HAVING DIFFERENT SLOPE SPEED—TRACTIVE EFFORT CURVES

Conditions: Rate of acceleration and braking 1.5 mi. per hr. per sec. Constant car friction 20 lb. per ton. No coasting, no leeway

A—Steep motor characteristic
B—Average motor characteristic
C—Flat motor characteristic

Next let us consider the effect of car friction on the average running speed. Referring to Fig. 4, a series of curves has been plotted using an average motor characteristic as determined in the above paragraphs. With a 75-mi. per hr. equipment, the average running speeds that can be made with car friction of 10, 20, 30, and 40 lb. per ton are respectively 33.6, 35.0, 35.5, and 36.0 mi. per hr. The per cent differences in average running speeds are respectively 4.2, 1.5, and 1.3. Practically all other curves of a similar nature have been based on 20 lb. per ton friction; hence, the error where the actual friction is 10 lb. per ton is 4.2 per cent, for 30 lb. per ton friction 1.5 per cent, and for 40 lb. per ton friction 2.8 per cent. We can eliminate this error by using the average motor characteristic and plotting curves for the various friction values encountered, in which case the maximum error in average running speed calculated from these curves should not exceed 1.4 per cent.

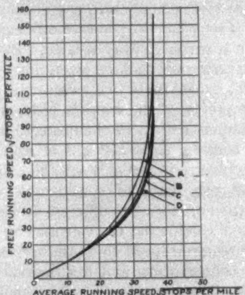

FIG. 4—CURVES ILLUSTRATING THE DIFFERENT FREE RUNNING SPEEDS REQUIRED WITH A MOTOR HAVING AN AVERAGE SLOPE SPEED—TRACTIVE EFFORT CURVE FOR VARIOUS CAR FRICTION VALUES

Conditions: Rate of acceleration and braking 1.5 mi. per hr. per sec. No coasting, no leeway, car friction constant at values given

A—10 lb. per ton car friction, B—20, C—30, D—40

Use: Abscissas are the values of average running speed times $\sqrt{\text{stops per mile}}$, and corresponding values of ordinate on friction curve divided by the $\sqrt{\text{stops per mile}}$ gives the free running speeds necessary to make the average running speed

The method by which curves of Fig. 3 and Fig. 4 were calculated is a development of the similar speed–time curve idea. For instance, if speed–time curves are calculated, using the average characteristic and a given rate of acceleration and braking for different lengths of run, a series of different shaped speed-time curves is obtained. The shortest run will be represented by a triangle, a slightly longer run will show the car accelerating according to the slope of motor characteristic and value of car friction and the longest run will be practically at free running speed. If a means is obtained for expressing each of these speed-time curves in terms of similar speed-time curves to give greater or less distance traversed, it will be possible to represent every existing running condition. How this is accomplished can be best explained by referring to Fig. 5.

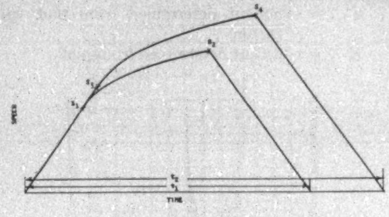

FIG. 5—SIMILAR SPEED—TIME CURVES

Let $D_1$ = distance traveled in $t_1$ seconds.

$D_2$ = distance traveled in $t_2$ seconds.

On an assumption that the two curves are similar, the following relations are true.

$$\frac{D_1}{D_2} = \left(\frac{S_1}{S_3}\right)^2 = \left(\frac{t_1}{t_2}\right)^2 = \left(\frac{V_1}{V_2}\right)^2 = \left(\frac{S_2}{S_4}\right)^2$$

where $V_1 = \frac{D_1}{t_1}$ and $V_2 = \frac{D_2}{t_2}$ = average running speed

or since $D_1 = \frac{5280}{\text{stops per mile}_1}$ and $D_2 = \frac{5280}{\text{stops per mile}_2}$

we can write $\frac{\text{stops per mile}_2}{\text{stops per mile}_1} = \left(\frac{S_1}{S_3}\right)^2 = \left(\frac{t_1}{t_2}\right)^2$

$$= \left(\frac{V_1}{V_2}\right)^2 = \left(\frac{S_2}{S_4}\right)^2$$

And by transposition, using an abreviation of stop per mile $S/M$,

$$\underline{S/M_1}\ S_1^2 = \underline{S/M_2}\ S_3^2$$

or $$\sqrt{S/M_1}\ S_1 = \sqrt{S/M_2}\ S_3 \quad (1)$$

and similarly $$\sqrt{S/M_1}\ V_1 = \sqrt{S/M_2}\ V_2 \quad (2)$$

$$\sqrt{S/M_1}\ t_1 = \sqrt{S/M_2}\ t_2 \quad (3)$$

$$\sqrt{S/M_1}\ S_2 = \sqrt{S/M_2}\ S_4 \quad (4)$$

Referring back to the different shaped speed-time curves, we can calculate $\sqrt{S/M_1}\ S_1$ and $\sqrt{S/M_1}\ V_1$ for each speed-time curve and plot a curve of (average running speed) × $\sqrt{\text{stops per mile}}$ against (speed on leaving control) × $\sqrt{\text{stops per mile}}$. Equations (**1**) and (**2**). $S_1$ of Fig. 6 shows such a curve based on the average characteristic. The value of $S_1$ is the product of (speed on leaving control) × $\sqrt{\text{stops per mile}}$. There is also shown a $S_2$ curve, the value of $S_2$ being (speed at which braking starts) × $\sqrt{\text{stops per mile}}$. Equation (**4**).

Thus, knowing the schedule speed required and the average length of run, the speed on leaving control can be calculated from Fig. 6 and a motor selected with a gear ratio such that it will have this speed at the tractive effort necessary to accelerate the car at the desired rate and at the average line voltage. However, this curve (Fig. 6) is not applicable to the tapped field motor because the speed on leaving control resistance points is quite different for a tapped and full field motor when

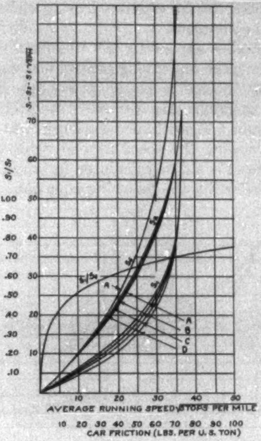

FIG. 6—CURVES FOR ESTIMATING SPEED AT END OF ACCELERATION, SPEED AT INSTANT OF BRAKING AND FREE RUNNING SPEED

$S_1$—Speed at end of acceleration times $\sqrt{\text{stops per mile}}$
$S_1/S_f$—Ratio of speed at end of acceleration to free running speed
$S_2$—Speed at which braking commences times $\sqrt{\text{stops per mile}}$
$S_f$—Free running speed times $\sqrt{\text{stops per mile}}$

A—10 lb. per ton car friction
B—20 lb. per ton car friction
C—30 lb. per ton car friction
D—40 lb. per ton car friction

Conditions: Rates of acceleration and braking 1.5 mi. per hr. per sec. No coasting, no leeway, car friction constant at values given

Use: For a given value of abscissas; the free running speed is equal to value of ordinate $S_1$ divided by the value of ordinate $S_1/S_f$ for proper car friction value and by $\sqrt{\text{stops per mile}}$, or to the value of ordinate $S_f$ divided by the $\sqrt{\text{stops per mile}}$; the speed at instant of braking is the value of ordinate $S_2$ divided by the $\sqrt{\text{stops per mile}}$

both motors are geared to make the same free running speed. In view of the fact that a tapped field motor will make practically the same schedule speed as a full field motor, each having the same free running speed, and also to the fact that the free running speed of a full field motor can be expressed accurately in terms of the speed on leaving control, a more practicable set of curves has been calculated showing the relation between (average running speed) $\sqrt{\text{stops}}$ per mile and (free running speed) $\sqrt{\text{stops}}$ per mile. From these curves the free running speed necessary to make a given schedule speed can be estimated using either a full or tapped field equipment.

The method of expressing the free running speed in terms of the speed on leaving control was suggested by Mr. E. E. Kimball's paper presented before the A. I. E. E. in 1908. Mr. Kimball noted that the tractive effort had a logarithmic relationship to speed and therefore knowing the speed at one value of tractive effort the speed could be calculated for any other value of tractive effort by the following equation.

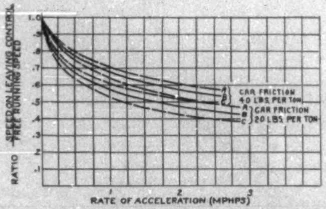

FIG. 7—CURVES ILLUSTRATING CHANGE IN RATIO OF SPEED ON LEAVING CONTROL TO FREE RUNNING SPEED WITH VARIOUS VALUES OF ACCELERATING RATES, CAR FRICTION, AND SLOPE OF MOTOR SPEED TRACTIVE EFFORT CURVES

A—Flat motor characteristic
B—Average motor characteristic
C—Steep motor characteristic

Formula $\frac{S_1}{S_f} = \sqrt[A]{\frac{p}{P}}$

Where $S_f$ = Free running speed mi. per hr.
$S_1$ = Speed on leaving control mi. per hr.
$A$ = Exponent expressing relationship between tractive effort and speed of motor characteristic
$p$ = Car friction at free running speed (lb. per ton)
$P$ = Tractive effort required to accelerate car at a given rate (lb. per ton)

$$S = S_0 \sqrt[3]{\frac{P_0}{P}} \qquad (5)$$

Where $S$ = speed at tractive effort $P$
$S_0$ = speed at tractive effort $P_0$

The cube root factor in Equation (**5**) represents the slope of the speed—tractive effort curve and as stated by Mr. Kimball was selected because of the ease of making certain calculations. The variation in this slope factor was determined by plotting speed against tractive effort on logarithmic paper for several motors varying in capacity. In the majority of cases the resultant curves were perfectly straight throughout the range of voltage and current that the motors would be normally used. Therefore, the logarithmic relationship between speed and tractive effort can be expressed by the following equation.

$$T\,E \times S^a = K \qquad (6)$$

where $T\,E$ = tractive effort (lb.)
$S$ = speed mi. per hr.
$a$ = exponent determined from plot (slope factor)
$K$ = constant determined from plot

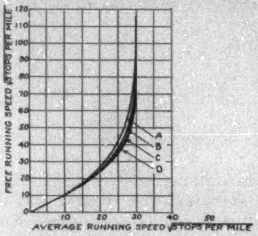

FIG. 8—CURVES FOR ESTIMATING FREE RUNNING SPEEDS

Conditions: Rate of acceleration and braking 1.0 mi. per hr. per sec. No coasting, no leeway, car friction constant for values given

Use: Abscissas are the values of average running speed times √ stops per mile and corresponding values of ordinate on friction curve divided by the √ stops per mile gives the free running speed necessary to make the average running speed

A—10 lb. per ton friction, B—20, C—30, D—40

The values of (a) varied between 2.8 and 3.5 representing, respectively, the steepest and flattest motor characteristics. A motor charcteristic having a slope factor of 3.2 represents the average slope of all motors considered and is that used as a basis of these curves.

Equation (**5**) shows that the ratio of speed on leaving control to free running speed depends on the slope of speed tractive effort curve, the car friction, and the rate of acceleration. Fig. 7 shows the variation of this ratio according to Equation (**5**). It is evident that with a given set of conditions the free running speed is a simple ratio of the speed on leaving control.

A set of curves based on different rates of acceleration and braking encountered in normal train operation, of (average running speed) $\sqrt{\text{stops}}$ per mile against (free running speed) $\sqrt{\text{stops}}$ per mile gives a ready means for determining the rates of acceleration and braking required and the free running speed necessary with those rates to make a given average running speed. Figs. 4, 8, and 9 show the character of such curves covering normal street car conditions.

As an illustrative example, suppose it is required to make a 37.5 mi. per hr. average running speed over average runs one mile long. By inspection of curves such speed cannot be made with 1 or 1.5 mi. per hr. per sec. accelerating and braking rates but with a 2.0 mi. per hr. per sec. rate of acceleration and braking a free running speed of 64 mi. per hr. per sec. is necessary assuming car friction at 20 lb. per ton. With this speed equipment it would be impossible to maintain an average running speed of 37.5 mi. per hr. over the usual roads due to traffic conditions and the fact that some coasting must occur. We shall, therefore, assume that an equipment to give a 5 per cent faster average running speed will take care of these delays. Our equipment must then be able to make 39.4 mi. per hr. average running speed when pushed to the limit and have a free running speed of 73 mi. per hr., according to Fig. 9, assuming car friction has increased to 25 lb. per ton.

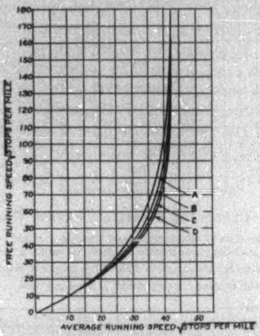

Fig. 9—Curves for Estimating Free Running Speeds

Conditions: Rate of acceleration and braking 2.0 mi. per hr. per sec. No coasting, no leeway, car friction constant for values given

A—10 lb. per ton car friction, B—20, C—30, D—40

Use: Abscissas are the values of average running speed times √ stops per mile and corresponding values of ordinate on friction curve divided by the √ stops per mile gives the free running speed necessary to make the average running speed

The curves as plotted were calculated on the assumption of a constant value of car friction from start to stop and are therefore only strictly accurate in the case where a car ascends a grade with no car friction. It is possible to plot the curves of free running speeds, r. m. s. current, and energy consumption using variable friction, but to do this involves the necessity of selecting an average friction curve. An examination of the many curves on car friction reveals not only a wide variation in friction values for the same car construction and weight, but also the ratio of car friction at end of accelerating period to that at the free running speed varies approximately as follows.

| | |
|---|---|
| Single motor cars | 0.55 to 0.40 |
| Multiple unit cars | 0.75 to 0.65 |

It is questionable, therefore, whether a single set of curves based on some average conditions of variable car friction would enable more accurate estimates to be made than using flat friction values.

The curves as calculated for constant friction values give results on the side of safety regarding free running speed, r. m. s. current, and energy consumption, if the actual car friction at free running speed is used. If values of r. m. s. current per ton and energy consumption are estimated on basis of car friction for speed at instant of braking, which is found from Fig. 4 curve $S_2$, a very close estimate of these values can be had.

By a similar manner in which the free running speeds have been obtained, the r. m. s. current can be estimated. Referring to Fig. 10, a series of curves gives the values of $A$ corresponding to the (average running speed) times $\sqrt{\text{stops per mile}}$. This factor is the actual value of (r. m. s. current per ton) times $\sqrt{\text{stops per mile}}$. The value r. m. s. current per motor as determined from curves must be either increased or decreased according to the average line voltage in question according to its variation from 600 volts on which the curves are based. The actual continuous rating of motor required is decreased from that estimated from curves when considering the duration of stop by the following relation.

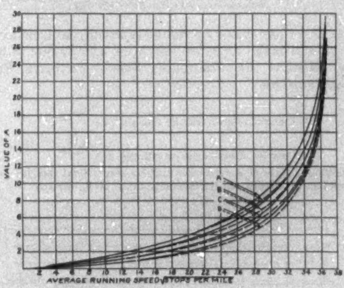

Fig. 10—Curves for Estimating Root-Mean-Square Currents for Specified Number of Stops per Mile and Schedule Speed

——————— Full field motor

- - - - - - - - Motor operating with 100 per cent & 60 per cent field

Conditions: Rate of acceleration and braking 1.5 mi. per hr. per sec. No coasting, no leeway

Use: Obtain value of ordinate $A$ on curve of car friction corresponding to average running speed $\sqrt{\text{stops per mile}}$ and apply in following formula

$$\text{R. m. s. current} = \sqrt{\left[\frac{\text{Value of } A}{\sqrt{\text{stops per mile}}} \times T \times \frac{600}{V}\right]^2 \left[\frac{t_1}{t_1\, t_s}\right]}$$

Where $T$ = tons per motor
$V$ = average line voltage
$t_1$ = time to make run excluding duration of stop (sec.)
$t_s$ = duration of stop (sec.)

A—40 lb. per ton friction
B—30 lb. per ton friction
C—20 lb. per ton friction
D—10 lb. per ton friction

$$I_1 = \sqrt{I_0^2\left(\frac{t_1}{t_1 + t_s}\right)} \qquad (7)$$

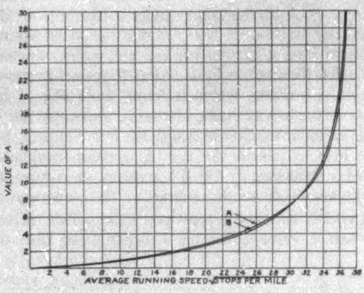

Fig. 11—Comparison of Root-Mean-Square Current for Specified Number of Stops per Mile and Schedule Speed With Motors of Different Speed—Tractive Effort Characteristics

A—Tractive effort varies as (mi. per hr.)$^{-\frac{1}{3.52}}$

B—Tractive effort varies as (mi. per hr.)$^{-\frac{1}{2.88}}$

Conditions: Rate of acceleration and braking 1.5 mi. per hr. per sec. No coasting, no leeway, car friction constant at 20 lb. per ton

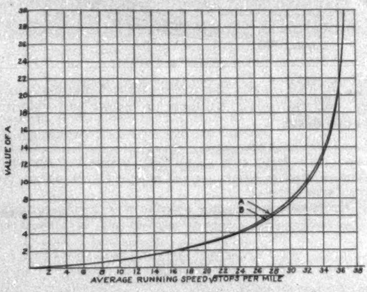

Fig. 12—Comparison of Root-Mean-Square Current for Specified Number of Stops per Mile and Schedule Speed With Motors of Different Speed—Tractive Effort Characteristics

A—Tractive effort varies as (mi. per hr.)$^{-\frac{1}{3.33}}$

B—Tractive effort varies as (mi. per hr.)$^{-\frac{1}{2.79}}$

Conditions: Rate of acceleration and braking 1.5 mi. per hr. per sec. No coasting, no leeway, car friction constant at 20 lbs. per ton

Where $I_1$ = r. m. s. current including time of stop
$I_0$ = r. m. s. current excluding time of stop (value obtained from curves)
$t_1$ = time to make run excluding stop (sec.)
$t_s$ = duration of stop (sec.)

An interesting comparison of the current required for a steep and flat motor characteristic can be made as shown on Figs. 11 and 12. This first curve is based on two motors having considerable differences in efficiency and shows that the steep characteristic motor demands less continuous capacity to perform a given schedule up to 30.9 than the motor with flat characteristic, but for greater values than 30.9 the condition reverses. Fig. 12 shows two motors having practically the same efficiency and favors the steep motor characteristic.

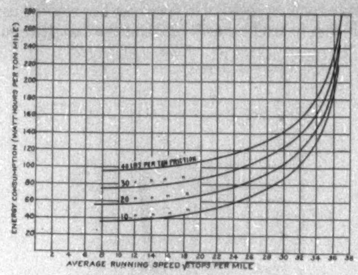

Fig. 13—Curves for Estimating Energy Consumption

Conditions: Rate of acceleration and braking 1.5 mi. per hr. per sec. No coasting, no leeway, car friction constant for values given

Use: Read energy consumption direct from proper friction curve corresponding to the average running speed √ stops per mile

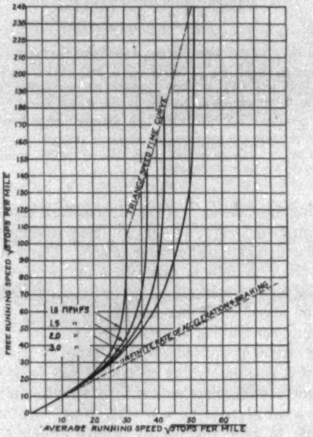

Fig. 14—Curves for Estimating the Increase in Average Running Speed With a Given Free Running Speed for Different Rates of Acceleration and Braking

Conditions: No coasting, no leeway, car friction constant at 20 lb. per ton

The curves of energy consumption on Fig. 13 are useful in determining the maximum energy consumption for a given schedule but as in case of the curves on r. m. s. currents they will not give accurate estimates unless a prediction can be made of the efficiency of the motor that will perform the service required.

The importance of making the best possible approximation of car friction is apparent on inspection of Figs. 10 and 13 for curves of r. m. s. currents and energy consumption, respectively. For example, assuming runs of one mile average length and an average running speed of 30 mi. per hr. the r. m. s. current per ton according to Fig. 10 is 7.4 for car friction of 20 lb. per ton and 6.3 for friction of 10 lb. per ton; a difference of 17.5 per cent. The energy consumption under same conditions is 105 watthour per ton mile for 20 lb. per ton car friction and 88 watthour per ton mile for 10 lb. per ton car friction; a difference of 19.2 per cent.

The greatest differences in average running speeds are those due to changes in the rates of acceleration and braking for cars having the same free running speeds. Fig. 14 shows these differences for rates between 1 and 3 mi. per hour per sec. It would appear from these curves that the highest rates would be the most advantageous, but we are limited to following considerations: first, comfort to passengers; second, in city service where high rates are desirable motors must be of light weight with small wheel diameters. This precludes use of large gear reduction or slow-speed motors with the present type of motor arrangement. Recent developments in the way of double reduction gearing and worm drive motors giving twice the normal reduction, permit the use of the higher rates of acceleration which Fig. 14 shows is desirable as it follows that with a lower free running speed, the motor capacity necessary is also less to perform a given service.

# Shunting of Track Circuit in a Polyphase System of Continuous Inductive Train Control

BY C. F. ESTWICK[1]
Member, A. I. E. E.

***Synopsis.**—Investigations into shunting of train control track circuits have been made in the field under operating conditions by observing the operation of the primary relay on a locomotive as a train runs into a track circuit in which there is a train ahead or an open switch and similar data have been obtained on the performance of the relay on trains in regular service.*

*It is intended in this paper to present a method for predetermining the shunting characteristics of train control track circuits. The system discussed is a polyphase system of continuous inductive train control with cab signals employed on double tracked steam roads. Curves are given which describe shunting conditions in train control track circuits and data are also given for comparison describing the shunting of the track relay on the same sections of track.*

IN a system of continuous inductive train control the apparatus on the trains on a steam operated railroad is located on the locomotive or tender and consists of a receiving system, visual cab signals, a train controlling mechanism that operates in connection with the automatic air brake equipment on the train, and auxiliary apparatus which include an acknowledging contactor and audible signals. The train controlling mechanism limits the speed of the train at all times to certain predetermined speeds which depend upon traffic conditions and the distance a train has traveled in a block. A failure on the part of the engineman to control the speed of the train properly results in an automatic application of the brakes as soon as the maximum allowable speed has been exceeded. After an automatic application has been made the brakes cannot be released until the speed of the train has been reduced below the maximum speed. When a train is traveling on clear track a clear signal indication is given in the cab and the speed of the train is limited to a safe speed which in the case of a passenger train may be 70 mi. per hr.; when the train enters a caution block the cab signal changes giving a caution or medium speed indication and the automatic controlling mechanism operates to enforce a gradual reduction in speed until the speed has been reduced to below 20 mi. per hr. at the exit end of the block. As a train passes from a caution into an occupied block the signal changes to a danger or slow-speed indication and the limitation of 20 mi. per hr. is maintained as long as the block is occupied by a train ahead.

The cab signals and speed controling mechanism are under the control of a three position a-c. primary relay. When the train is traveling under clear conditions the relay is in its normally energized position; when the train passes into a caution block the relay operates to the reverse position and when it is in an occupied block or a block in which there is an open switch the relay assumes its deenergized position and releases the normal or reverse contacts. The primary relay is under the control of an influence obtained inductively, by means of receivers on the locomotive, from alternating current flowing in the rails of the track.

The apparatus along the track includes the usual a-c. track circuit, modified slightly for train control purposes, and upon this is superimposed a so-called "line circuit." The actual current flowing in the rails consists of two components of current, one due to a voltage impressed on the circuit from the track circuit transformer and the other is due to voltage from a transformer in the line circuit. These two components of currents will be considered separately and will be referred to hereafter simply as "track circuit current" and "line circuit current." The wayside circuits are shown schematically in the diagram in Fig. 1 and may be traced as follows:—Track circuit current flows from the track circuit transformer which is located at the exit end of the block through a limiting impedance and a pole changer to one of the rails of the track, along the rail to the opposite end of the block through a variable resistance unit and windings of the track relay to the other rail, back along the rail and through the pole changer to the transformer. The relay is normally energized by current flowing in the track and local windings as shown in the diagram; the track windings receive current from the rails and the local windings

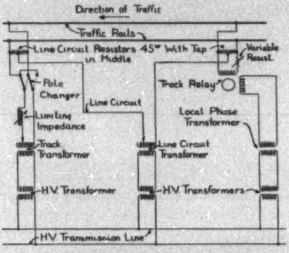

FIG. 1—TRAIN CONTROL TRACK CIRCUIT

*Presented at Northeastern District No. 1 Meeting of the A. I. E. E., New Haven, Conn., May 9-12, 1928.*

are energized by current from the local phase transformer. The track relay is the usual a-c. rotor type relay employed in railroad signaling which operates in three positions and requires the use of the pole changer in the track circuit to give normal and reverse operation. The normal and reverse control also permits of three position operation of the primary relay which is a similar two element relay of the rotor type. When a block is occupied by a train the current in the rails flows from one rail to the other through the wheels and axles of the train and on account of the very low impedance of the path through the wheels and axles most of the current is shunted from the track relay which causes it to become deenergized sufficiently to release its front contacts. Circuits through the relay contacts control the operation of wayside signals in the usual manner. Line circuit current flows from the line circuit transformer to the middle point of a comparatively high resistance bridged across the rails at the relay end of the block, through the two halves of the resistance and along the rails of the track in multiple, through a similar resistance at the other end of the block to the middle point of the resistance unit and through a line wire back to the transformer. From the description of the circuits it is evident that track circuit current flows away from the transformer on one rail of the track and back on the other rail, that is, the current flows in opposite directions in the two rails whereas the line circuit current is evenly divided between the rails and flows in the same direction in each rail. The track circuits are adjusted for normal operation under clear or caution conditions so that there will be 0.8 ampere in the rails at the relay end of the circuit as a train enters the block and the line circuit is adjusted to give total line circuit current 0.8 ampere or 0.4 ampere in each rail.

There are two receivers located on the locomotive just ahead of the front wheels called track circuit receivers and a similar pair of receivers farther back on the locomotive or on the tender known as line circuit receivers. The receivers are supported a few inches above the rails of the track and coils in each pair of receivers are connected in series. The connections are such that, on account of the direction of the flow of current in the rails, the track circuit receivers are energized inductively by track circuit current and are not influenced by line circuit current and the line circuit receivers are energized by line circuit current and are not affected by current in the track circuit. There is a two-circuit vacuum tube amplifier with four tubes employed in the locomotive equipment to amplify the small voltages induced in the receiver coils. The input circuits of the amplifier are connected separately to the front and rear receivers and the output circuits are connected to corresponding windings of the primary relay. The amplifying apparatus is carefully adjusted so that when the track circuit and line circuit currents in the rails are in time phase, the currents in the relay windings will also be in phase in which case no torque will be developed on the rotor shaft of the relay. If the phase of the current in either the track circuit or the line circuit is varied the corresponding current in the relay follows the phase of the rail current. The phase displacement between the currents in the relay windings under any condition of operation is therefore the same as the phase displacement between the currents in the rails. The size of the current in the relay windings relative to the corresponding rail currents is shown in Fig. 2.

*Conditions of the Track.* The rails of the track are A. S. C. E. section, 100 lb. per yd., bonded with 2 No. 6 copper-clad bond wires 54 in. long having a loop impedance 0.25 ohm per 1000 ft., power factor 0.5, and the ballast is mostly stone ballast having a resistance varying between 5 ohms and 20 ohms per 1000 ft. of track. The leakage resistance of two rails in multiple to ground is taken as 2 ohms per 1000 ft. in wet weather and 12 ohms per 1000 ft. in dry weather. The length of the track circuit is 6000 ft.

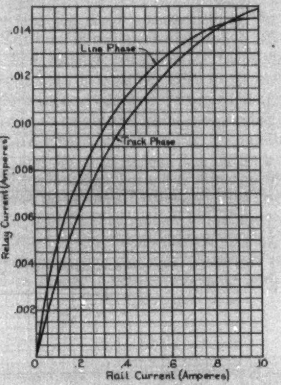

FIG. 2—RELATION BETWEEN CURRENT IN THE RELAY AND CURRENT IN THE RAILS

*Characteristics of the Track Relay.* Local Phase: Impedance 440 ohms, power factor 0.656; current at 110 volts, 0.25 ampere; phase of current relative to voltage ⦢ 49 deg.

NOTE: The inverted angle sign ⦢ indicates a lagging current or voltage whereas the usual angle sign ∠ indicates a leading current or voltage relative to the voltage at the secondary of the transformer. This notation will be employed hereafter in tabulating currents or voltages to describe phase relations.

Track Phase: Impedance 0.64 ohm, power factor 0.656; operating currents with 90 deg. phase displacement. Current to pick up relay to make front stop, 0.22 ampere. Current to pick up relay to close front contacts, 0.19 ampere. Current to allow relay to release its contacts, 0.11 ampere.

*Adjustment of the Track Circuit.* On a steam operated road without train control, the track circuit would be adjusted under wet weather conditions with a limiting impedance of 4 ohms but with this adjustment when a train is entering the block there would not be the required current 0.8 ampere in the rails for the operation of the train control equipment. To increase the current in the rails the amount of limiting impedance might be reduced but it would be better for the purpose of improving the shunting, to retain the 4 ohms limiting impedance and increase the voltage on the track trasformer to give 0.88 ampere, (*i. e.,* 0.8 ampere + 10 per cent to allow for drop in transmission line voltage) and insert a variable resistance in series with the track relay as shown in Fig. 1 to limit the current in the relay sufficiently to give satisfactory normal operation.

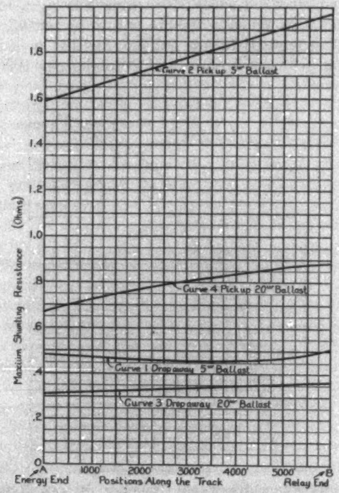

FIG. 3—MAXIMUM SHUNTING RESISTANCES AFFECTING THE TRACK RELAY AS A TRAIN PASSES THROUGH THE BLOCK

Without considering train control, minimum operation of the track relay would be obtained with 3.1 volts at the transformer giving a current 0.26 ∠ 117 deg. 33 min. ampere in the relay but to get sufficient current in the rails for train control operation the voltage will have to be increased to 7 volts which gives 0.875 ∠ 106 deg. 41 min. ampere in the rails as a train enters the block. The variable resistance in series with the relay is then adjusted when the block is unoccupied to 1.75 ohms giving 0.316 ∠ 101 deg. 24 min. ampere in the relay (equivalent current at 90 deg. phase displacement 0.25 ampere). With this adjustment in dry weather when the ballast resistance is 20 ohms per 1000 ft. the current in the relay will increase to 0.706 ∠ 75 deg. 7 min. ampere (equivalent current at 90 deg. phase displacement 0.311 ampere) and the current in the rails at the relay end of the circuit as a train enters the block will be 1.185 ∠ 85 deg. 34 min. amperes.

*Shunting of the Track Relay.* Ordinarily with a properly adjusted track circuit when a train enters a block the track relay becomes shunted but in the case of a poorly adjusted circuit under adverse rail conditions it might happen that the relay would not shunt or if the relay shunts properly as a train enters a high shunting resistance might allow the relay to pick up and the train loses its shunt. To determine the shunting characteristics of the track circuit, calculations have been made which show the maximum shunting resistance which will cause the relay to release its contacts and also the resistance which will just allow the relay to pick up again as the train passes through the block. The curves 1 and 3 in Fig. 3 show the maximum shunting resistances for different positions along the track throughout the entire length of the block which will cause the relay to release its contacts and curves 2 and 4 resistances which will allow the relay to pick up to just close its front contacts.

In Table I numerical values are given of the data shown on the curves and also values of current in the relay when the corresponding maximum shunting resistances are connected across the rails. The formulas employed in calculating these maximum shunting resistances at intermediate positions in the block are given in Appendix I.

*Characteristics of the Primary Relay.* Operating torque on rotor shaft with 90 deg. phase displacement:

To cause sector to operate to front stop 0.45 in. - oz.
To pick up to just make front contacts 0.38 in. - oz.
To release front contacts 0.24 in. - oz.

The relation between torque and currents in the relay is expressed by the following equation:

$$T = I_L I_T K \sin \phi$$

Where T = Torque on rotor shaft
$I_L$ = Current in line phase
$I_T$ = Current in track phase
$\phi$ = Difference in phase between $I_L$ and $I_T$
$K$ = 4500

The value of $K$ is practically constant for all operating conditions.

If the size of the line circuit current in the rails is known at any position on the track the operating current in the rails in the track circuit can be determined at 90 deg. phase displacement to produce any required torque in the primary relay. To accomplish this, knowing the line current in the rails, the corresponding current in the relay is determined from curves in Fig. 2 and knowing the torque (as given above for pick-up and drop-away conditions) the current in the track

TABLE I

MAXIMUM SHUNTING RESISTANCE AS AFFECTING OPERATION OF THE TRACK RELAY

| | 5 ohm ballast | | | |
|---|---|---|---|---|
| | Maximum shunting resistance (ohms) | | Current in relay when shunt is applied (amperes) | |
| Positions along the track | Pick-up | Drop-away | Pick-up | Drop-away |
| At *A* end | 1.585 | 0.485 | 0.21 ∠ 115 deg. 11 min. | 0.113 ∠ 126 deg. 20 min. |
| 1500 ft. from *A* | 1.68 | 0.468 | 0.21 ∠ 110 deg. 20 min. | 0.116 ∠ 120 deg. 6 min. |
| 3000 ft. from *A* | 1.783 | 0.459 | 0.223 ∠ 107 deg. 39 min. | 0.121 ∠ 114 deg. 17 min. |
| 4500 ft. from *A* | 1.87 | 0.464 | 0.224 ∠ 107 deg. 23 min. | 0.122 ∠ 113 deg. 19 min. |
| At *B* end | 1.97 | 0.505 | 0.225 ∠ 106 deg. 28 min. | 0.123 ∠ 112 deg. 46 min. |

| | 20 ohm ballast | | | |
|---|---|---|---|---|
| | Maximum shunting resistance (ohms) | | Current in relay when shunt is applied (amperes) | |
| Positions along the track | Pick-up | Drop-away | Pick-up | Drop-away |
| At *A* end | 0.672 | 0.314 | 0.227 ∠ 105 deg. 51 min. | 0.123 ∠ 112 deg. 3 min. |
| 1500 ft. from *A* | 0.75 | 0.327 | 0.251 ∠ 98 deg. 10 min. | 0.134 ∠ 104 deg. 5 min. |
| 3000 ft. from *A* | 0.81 | 0.34 | 0.263 ∠ 95 deg. 30 min. | 0.141 ∠ 99 deg. 30 min. |
| 4500 ft. from *A* | 0.855 | 0.356 | 0.275 ∠ 92 deg. 44 min. | 0.148 ∠ 97 deg. 4 min. |
| At *B* end | 0.887 | 0.366 | 0.29 ∠ 89 deg. 53 min. | 0.156 ∠ 93 deg. 51 min. |

circuit windings of the relay can be determined from the above formula. The track circuit rail current is then determined from the curve. Numerical values of track circuit currents to give pick-up and drop-away of the relay with a train at different positions on the track will be given after a study has been made of the line circuit.

*Current in the Rails under the Receivers.* Most of the current in the line circuit flows through the rails in multiple but there is a small amount of current that flows through the ground as shown in Fig. 4. The leakage current flows from the rails to ground in one-half of the circuit from *A* to *C* and flows back from the ground into the rails in the other half of the circuit from *C* to *B*. Tests have been made in the field of the amount of current flowing in the rails throughout the length of a block with a vacuum tube testing apparatus used in connection with a search coil on a laminated iron structure that was placed over the rail. The curves obtained show that the current in the rails follows very closely to the shape of the common catenary or cosh curve and for that reason the conductance to ground is assumed to be evenly distributed and line circuit currents have therefore been computed from well known hyperbolic formulas. The condition shown in Fig. 4 may also be represented as shown in Fig. 5 in which the ground is assumed to have zero resistance and is represented as a neutral plane. For uniformity in the use of formulas in making calculations the line circuit may be considered as if it were a two-conductor circuit 3000 ft. in length having evenly distributed leakage giving the same attenuation in Fig. 5 as in Fig. 4. The loop impedance is taken as 0.125 ohm per 1000 ft., and leakage resistance of twice the values given above, *i. e.*, 4 ohms per 1000 ft. in wet weather and 24 ohms in dry weather. The attenuation in the latter case is so small that it may be neglected. The complete line circuit shown in Fig. 1 contains mostly resistance and for that reason the current from the transformer as it enters the rails at either end of the block is assumed to be in phase with the voltage at the transformer and it is further assumed that the voltage at the secondaries of the transformers supplying the track and line circuits and the local circuit of the track relay are in phase. Calculations have been made of the line circuit current in the rails at different positions along the track and the results are given in Table II. The table also shows corresponding values of current in the relay taken from the curves in Fig. 2.

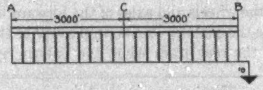

FIG. 4—EVENLY DISTRIBUTED LEAKAGE BETWEEN TWO RAILS IN MULTIPLE AND GROUND

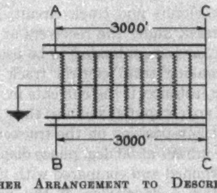

FIG. 5—ANOTHER ARRANGEMENT TO DESCRIBE CONDITION SHOWN IN FIG. 4

Having determined the line circuit currents in the relay and knowing the torque characteristics the corresponding currents in the track circuit windings can be determined by use of the formula given above assuming 90 deg. phase displacement. For a train at different positions on the track numerical values of the current have been computed to cause the relay to operate to its front stop, to pick up to just close its front contacts, and to release the contacts. These

TABLE II

LINE CIRCUIT CURRENT IN THE RAILS AND CORRESPONDING CURRENT IN THE RELAY

Ballast 5 Ohms per 1000 ft.

| Positions along the track | Currents in rails | Current in relay |
|---|---|---|
| At *A* end........ | 0.88 ∠ 0 deg. ampere | 0.0144 ampere |
| 1000 ft. from *A*.. | 0.87 ∠ 1 deg. ampere | 0.01435 ampere |
| 2000 ft. from *A*.. | 0.86 ∠ 3 deg. ampere | 0.0143 ampere |
| 3000 ft. from *A*.. | 0.817 ∠ 6 deg. 30 min. ampere | 0.0142 ampere |
| 4000 ft. from *A*.. | 0.86 ∠ 3 deg. ampere | 0.0143 ampere |
| 5000 ft. from *A*.. | 0.87 ∠ 1 deg. ampere | 0.01435 ampere |
| At *B* end........ | 0.88 ∠ 0 deg. ampere | 0.0144 ampere |

Ballast 20 ohms per 1000 ft.

In this case the current in the rails at any position on the track is 0.88 ∠ 0 deg. ampere and the current in the relay is 0.0144 ampere.

| 4000 ft. from *A*........ | 0.007 | 0.235 | 0.00592 | 0.188 | 0.00373 | 0.112 |
| 5000 ft. from *A*........ | 0.00697 | 0.234 | 0.00589 | 0.187 | 0.00372 | 0.111 |
| At *B* end.............. | 0.00695 | 0.233 | 0.00587 | 0.186 | 0.0037 | 0.11 |

values are given in Table III together with corresponding track circuit currents in the rails which have been taken from the curves in Fig. 2. In making track circuit calculations to determine the performance of a track relay the pick-up and drop-away characteristics are usually given in terms of the current in the track and local windings of the relay at 90 deg. phase displacement. The data in Tables II and III give the operating characteristics of the primary relay in terms of line circuit and track circuit current in the rails of the track under the receivers at 90 deg. phase displacement, and are intended to be used in a similar manner in making train control track circuit calculations. For instance, if the currents in the rails under the receivers are computed and also their phase relation for a train at any position on the track, the equivalent track circuit current at 90 deg. phase displacement may then be determined and compared with the data in the tables to obtain a knowledge of the performance of the relay.

In this discussion the data in the tables have been employed in connection with formulas given in Appendix II in making calculation of the shunting characteristics of the circuit.

*Shunting of the Track as Affecting the Primary Relay.* In a train control track circuit energy is always fed to the rails at the end of the block ahead of the train when the block is occupied. If a shunt is connected across the rails at any position in the block in advance of the train the track circuit current would flow through the shunt path and there would be practically no track circuit current under the receivers on the train with the result that the primary relay would become deenergized and release its contacts. The operation of the relay would immediately start the train controlling mechanism in operation to control the speed of the train automatically. In practise a shunt across the rails may be through a circuit controller at an open switch or it may be due to a train ahead in the same block.

Two conditions of shunting have been considered; first, with a forward train the middle of the block and the following train entering and approaching the train ahead; second, with a forward train at the exit end of the block and the rear train entering and proceeding into the block. The most difficult condition of shunting has been considered in which it is assumed that the resistance through the wheels and axles on the rear train is negligible. In each case calculations have been made to determine the maximum shunting resistance through the wheels and axles of the forward train which will cause the pick-up or the drop-away of the primary relay on the rear train when the ballast resistance is 5 ohms and also when it is 20 ohms per 1000 ft. of track. The results of the calculations are plotted in curves in Figs. 6 and 7. Curves in Fig. 6 are for the case where the forward train is in the middle of the block and Fig. 7 where the forward train is at the leaving end of the block. In both figures, curves 1 and 2 show the maximum resistances of the shunt of the forward train which

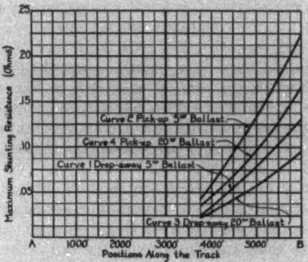

Fig. 6—Curves Showing Maximum Shunting Resistances When Forward Train is in the Middle of a Block and a Following Train is Entering and Approaching From the Relay End

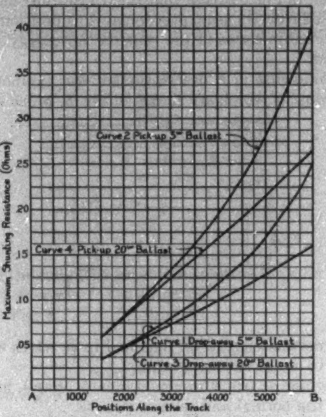

Fig. 7—Curves Showing Maximum Shunting Resistance When Forward Train is at the Energy End of a Block and a Following Train Entering and Approaching From the Relay End

will prevent the relay on the rear train from picking up and the resistances which will cause the relay to drop away respectively when the ballast is 5 ohms per 1000 ft. and curves 3 and 4 give the maximum resistances when the ballast is 20 ohms per 1000 ft. Numerical data from which these curves are plotted and also corresponding values of track circuit current in the rails under the receivers on the rear train are given in Tables IV and V.

The method of making these shunting calculations in train control track circuits is described in Appendix II.

## Conclusions

In Fig. 3 the curves 3 and 4 describe the shunting of the track relay as a train passes through the block during dry weather conditions. The resistance of the shunt must be less than 0.366 ohm as shown on curve 3 when the train enters the block to cause the relay to release its contacts and as the train proceeds the resistance must remain less than the resistances shown on curve 4 to prevent the relay from picking up. If the relay should pick up, the shunting resistance must decrease again below the values shown on curve 3 to cause the relay to release its contacts.

The curves in Figs. 6 and 7 describe the shunting

| 2000 ft. from *A*........ | 0.083 | 0.050 | 0.261 ∠ 138 deg. 28 min. | 0.163 ∠ 137 deg. 38 min. |

requirements for safe operation of the train control equipment. For instance, during dry weather conditions when there is a train in the middle of a block and a following train is entering the block, curve 3 in Fig. 6 shows that the resistance of the shunt of the forward train must be less than 0.096 ohm to cause the primary relay on the rear train to release its contacts and the resistance must remain less than the values shown on curve 4 to prevent the relay from picking up as the train proceeds into the block. If the relay should pick-up the shunting resistance must be reduced to a value less than those shown on curve 3 to cause the relay to drop away again.

In the ordinary track circuit, the wheels of a train shunt out the track relay in series with the rails of the track but in the case of a forward train shunting current from a rear train there is only the impedance of the rails between the two trains and the impedance through the wheels and axles of the rear train to be shunted. The effect of the shunting on the primary relay is not as good as the shunting of the track relay and the shunting effect on the primary relay on a following train becomes poorer as the train runs closer to the train ahead.

In short train control track circuits, the condition of the ballast has little effect on the shunting of the primary relay but in longer circuits, a mile or more in length, the ballast resistance has a considerable effect. The curves show that the shunting is better during wet weather than it is under dry weather conditions.

## Appendix I

### INTERMEDIATE SHUNTING IN A-C. STEAM ROAD TRACK CIRCUITS

It is possible to determine the maximum shunting resistance in either a-c. steam or electric road track circuits by using the general formula for shunting.

$$G = \frac{E\,Y}{I_S} - K$$

This formula in either case may be employed when a shunt is connected at either end of a track circuit or at any intermediate position along the track. In solving any problem for shunting it is first necessary to determine the values of $Y$ and $K$ and for this purpose formulas have been given in a previous article[2] for determining these values in a steam road track circuit in cases where the shunt is applied at either end of the circuit. It is intended in this appendix to derive the formulas for $Y$ and $K$ that have been used in making calculations of shunting of the track relay at intermediate positions along the track.

The diagram in Fig. 8 is the ordinary steam road track circuit in which $A\,B$ is a track section to which there is a shunt connected across the rails at an intermediate position $C$. The circuit shown in Fig. 9 is the same as the circuit in Fig. 8 except that the transformer has been transposed from its usual position at $A$ to position $C$ and is connected in series in the rails on the energy side of the shunt.

The following is a description of the symbols employed most of which are shown in Fig. 8, which we will call the normal circuit, or that in Fig. 9, which will be referred to as the reverse circuit.

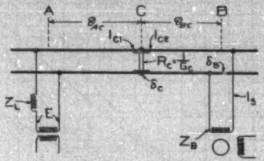

FIG. 8

$E$ = voltage at transformer (standard phase), in both the normal and reverse circuits.

$i$ = equivalent current in the relay at 90 deg. phase displacement, which will just cause the relay to drop away or in determining loss of train shunt it is the value of current which just allows the relay to pick up sufficiently to make its contacts.

$G_C$ = minimum shunting conductance when a shunt is applied at $C$.

$R_C$ = maximum shunting resistance when shunt is applied at $C$.

The above quantities are considered as real quantities whereas those that follow are complex quantities.

$Z_B$ = impedance of relay and leads to track.

$Z_L$ = limiting impedance including leads to track.

$z_0$ = surge impedance of the track.

$\theta$ = hyperbolic angle subtending portions of the track as indicated by subscripts.

$\delta_B = \tanh^{-1} \dfrac{Z_B}{z_0}$ = position angle at $B$ in normal circuit

$\delta_C = \delta_B + \theta_{BC}$ = position angle at $C$ in normal circuit

$I_S$ = current in relay when shunt is applied.

$I_{C_2}$ = current in rails on relay side of shunt in normal circuit.

$I_{C_1}$ = current in rails on energy side of shunt in normal circuit.

$\delta_A' = \tanh^{-1} \dfrac{Z_L}{z_0}$ = position angle at $A$ in reverse circuit.

$\delta_C' = \delta_A' + \theta_{AC}$ = position angle at $C$ in reverse circuit.

$I_A'$ = current in limiting impedance in reverse circuit.

$I_{C_1}'$ = current flowing through transformer in reverse circuit (impedance of transformer secondary is assumed negligible).

---

[2] *Shunting in A-C. Track Circuits*, By C. F. Estwick, A. I. E. E. JOURNAL, December 1921, p. 919.

From the theory of the reverse circuit it will be understood that the current $I_{C1}$ in Fig. 8 is the same as current $I_A'$ in the reverse circuit in Fig. 9. With this principle in mind the following algebraic solution may be understood by reference to the diagrams.

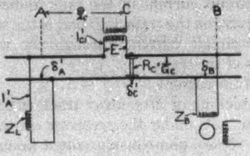

Fig. 9

From Fig. 8

$$I_{C2} = I_S \times \frac{\cosh \delta_C}{\cosh \delta_B} \tag{1}$$

and from Fig. 9

$$I_{C1}' = \frac{E}{\dfrac{R_C\, z_0 \tanh \delta_C}{R_C + z_0 \tanh \delta_C} + z_0 \tanh \delta_C'} \tag{2}$$

and $$I_{C1} = I_A' = I_{C1}' \times \frac{\cosh \delta_A'}{\cosh \delta_C'} \tag{3}$$

From Fig. 8

$$I_{C2} = I_{C1} \times \frac{R_C}{R_C + z_0 \tanh \delta_C} \tag{4}$$

Combining the above equations

$$I_S \times \frac{\cosh \delta_C}{\cosh \delta_B} = \frac{E}{\dfrac{R_C\, z_0 \tanh \delta_C}{R_C + z_0 \tanh \delta_C} + z_0 \tanh \delta_C'} \times \frac{\cosh \delta_A'}{\cosh \delta_C'} \times \frac{R_C}{R_C + z_0 \tanh \delta_C} \tag{5}$$

Simplifying the second member

$$I_S \times \frac{\cosh \delta_C}{\cosh \delta_B} = \frac{E\, R_C}{R_C (z_0 \tanh \delta_C + z_0 \tanh \delta_C') + z_0^2 \tanh \delta_C \tanh \delta_C'} \times \frac{\cosh \delta_A'}{\cosh \delta_C'} \tag{6}$$

For simplicity substitute

$$a = \frac{\cosh \delta_C}{\cosh \delta_B} \quad b = z_0 \tanh \delta_C \quad c = z_0 \tanh \delta_C'$$

$$d = \frac{\cosh \delta_A'}{\cosh \delta_C'} \tag{6a}$$

Then $$I_S\, a = \frac{E\, R_C\, d}{R_C (b + c) + b\, c} \tag{7}$$

Remembering that $G_C = 1/R_C$

$$I_S\, a = \frac{E\, d}{G_C\, b\, c + (b + c)} \tag{8}$$

Whence $$G_C = \frac{E\, d}{I_S\, abc} - \frac{b + c}{bc} \tag{9}$$

Expanding we have

$$G_C = \frac{E \cosh \delta_A' \cosh \delta_B}{I_S \cosh \delta_C \cosh \delta_C'\, z_0^2 \tanh \delta_C \tanh \delta_C'} - \frac{z_0 (\tanh \delta_C + \tanh \delta_C')}{z_0^2 \tanh \delta_C \tanh \delta_C'} \tag{10}$$

or $$G_C = \frac{E \cosh \delta_A' \cosh \delta_B}{I_S\, z_0^2 \sinh \delta_C \sinh \delta_C'} - \frac{\tanh \delta_C + \tanh \delta_C'}{z_0 \tanh \delta_C \tanh \delta_C'} \tag{11}$$

This formula is used for determining the minimum conductance or maximum resistance of a shunt at an intermediate position on the track.

When the shunt is transferred to the $A$ end of the track, this formula reduces to

$$G_A = \frac{E \cosh \delta_B}{I_S\, Z_L\, z_0 \sinh \delta_A} - \frac{Z_L + z_0 \tanh \delta_A}{Z_L\, z_0 \tanh \delta_A} \tag{12}$$

And when the shunt is at the $B$ end the formula becomes

$$G_B = \frac{E \cosh \delta_A'}{I_S\, Z_B\, z_0 \sinh \delta_B'} - \frac{Z_B + z_0 \tanh \delta_B'}{Z_B\, z_0 \tanh \delta_B'} \tag{13}$$

From the above formula for intermediate shunting we then have

$$Y = \frac{\cosh \delta_A' \cosh \delta_B}{z_0^2 \sinh \delta_C \sinh \delta_C'} \tag{14}$$

$$K = \frac{\tanh \delta_C \tanh \delta_C'}{z_0 \tanh \delta_C \tanh \delta_C'} \tag{15}$$

Having determined $Y$ and $K$ the maximum shunting resistances and corresponding currents in the relay can be computed in the manner already described in the previous article referred to above, however, to make this discussion more complete the formulas employed are given below.

Let $\gamma$ = Slope of track phase current in relay (degrees)
$\beta$ = Slope of local phase current in relay (degrees)
$\phi = \beta - \gamma$ = Phase displacement (degrees)
$y$ = Size of $Y$
$v$ = Slope of $Y$ (degrees)

$m$, $n$, $e$, and $f$ are numerical values obtained from the following equations

$$\frac{E\, y}{i} \angle (v - \beta) = m + j\, n \text{ and } - K = e + j\, f \tag{16}$$

Then, when $\phi$ is positive (as it is in all cases considered above),

$$G_C = e - \frac{n}{2} \pm \sqrt{\left(\frac{n}{2}\right)^2 - mf - f^2} \qquad (17)$$

In this formula the proper sign before the radical is used to determine $G_C$ as a positive quantity.

Then $R_C = 1/G_C$

$$\gamma = v - \tan^{-1}\left(\frac{-f}{G_C - e}\right) \qquad (18)$$

and

$$I_B = \frac{i}{\sin \phi} \angle \gamma \qquad (19)$$

In the last formula $\sin \phi$ is always taken as positive.

Numerical examples given in the previous paper will show more clearly how these formulas are employed.

## Appendix II

### SHUNTING IN TRAIN CONTROL TRACK CIRCUITS

In the train control track circuit shown schematically in the diagram Fig. 10 there are two trains in the block at positions $C$ and $D$. It is required to determine the resistance of the shunt through the wheels and axles of the train at $C$ which will just cause the primary relay on the train at $D$ to release its front contacts or the resistance of the shunt which will just allow the relay to pick up and close the contacts. The resistance of the shunt of the following train at $D$ is assumed to be negligible and short-circuits the track relay and the rails in the rear of the train. The formulas for shunting are derived in a manner very similar to those in Appendix I for shunting of the track relay at an intermediate position in the block. If the line circuit in Fig. 10 is neglected it can be seen that the circuit in Fig. 11 is the same as the circuit in Fig. 10 except that the transformer has been transposed from its normal position at $A$ in Fig. 10 to position $C$ as shown in Fig. 11. The symbols employed herein are the same as those in Appendix I except as follows:

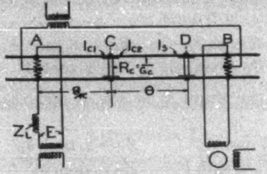

FIG. 10

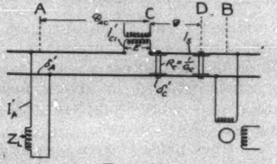

FIG. 11

$I_B$ = track circuit current in the rails under the front receivers on the train at $D$ and is the same as the short-circuit current through the wheels and axles of the train.

$\gamma$ = slope of the current $I_B$.

$i$ = size of pick-up or drop-away track circuit current in the rails under the receivers on the train at $D$ at 90 deg. phase displacement taken from the second and third columns in Table III.

$\beta$ = slope of line circuit current in the rails under the rear receivers on the train at $D$ given in the second column in Table II.

$\theta$ = hyperbolic angle subtending the length of track from $C$ to $D$.

$\delta_B$ and $\delta_C$ are not employed in this case.

Referring to the diagram in Fig. 10 we have

$$I_{C2} = I_B \cosh \theta \qquad (1)$$

and from Fig. 11

$$I_{C1}' = \frac{E}{\dfrac{R_C\, z_0 \tanh \theta}{R_C + z_0 \tanh \theta} + z_0 \tanh \delta_C'} \qquad (2)$$

It will be understood that $I_{C1}$ in Fig. 10 is equal to $I_A'$ in Fig. 11, therefore,

$$I_{C1} = I_A' = I_{C1}' \times \frac{\cosh \delta_A'}{\cosh \delta_C'} \qquad (3)$$

From Fig. 10

$$I_{C2} = I_{C1} \times \frac{R_C}{R_C + z_0 \tanh \delta_C} \qquad (4)$$

Combining the above equations,

$$I_B \cosh \theta = \frac{E}{\dfrac{R_C\, z_0 \tanh \theta}{R_C + z_0 \tanh \theta} + z_0 \tanh \delta_C'} \times \frac{\cosh \delta_A'}{\cosh \delta_C'} \times \frac{R_C}{R_C + z_0 \tanh \theta} \qquad (5)$$

This equation is similar to equation (5) in Appendix I and treated in the same manner gives the following equations for the minimum conductance of the shunt of the train at $C$

$$G_C = \frac{E \cosh \delta_A'}{I_B\, z_0^2 \sinh \theta \sinh \delta_C'} - \frac{\tanh \theta + \tanh \delta_C'}{z_0 \tanh \theta \tanh \delta_C'} \qquad (6)$$

Whence

$$Y = \frac{\cosh \delta_A'}{z_0^2 \sinh \theta \sinh \delta_C'} \qquad (7)$$

and

$$K = \frac{\tanh \theta + \tanh \delta_C'}{z_0 \tanh \theta \tanh \delta_C'} \qquad (8)$$

When the forward train is at $A$ these formulas reduce to

$$G_A = \frac{E}{I_S Z_L z_0 \sinh\theta} - \frac{Z_L + z_0 \tanh\theta}{Z_L z_0 \tanh\theta} \qquad (9)$$

$$Y = \frac{1}{Z_L z_0 \sinh\theta} \qquad (10)$$

$$K = \frac{Z_L + z_0 \tanh\theta}{Z_L z_0 \tanh\theta} \qquad (11)$$

After determining the values of $Y$ and $K$, the solution is completed in the same manner as in Appendix I employing the formulas (**16**) to (**19**).

*Numerical Example.* As an example, consider a case of shunting in which there are two trains in a block, the forward train being in the middle of the section and the following train a distance of 2000 ft. in the rear of the train ahead or at a point 1000 ft. from the entrance end of the block. It is required to determine the maximum shunting resistance through the wheels and axles of the forward train which will cause the primary relay on the rear train to release its front contacts. The loop impedance of the rails is 0.25 ohm per 1000 ft., the ballast resistance from rail to rail is 5 ohms per 1000 ft. and the resistance of the ballast from two rails in multiple to ground is 2 ohms per 1000 ft. of track. The voltage at the line circuit transformer is adjusted so that the total line circuit current from the transformer is 0.88 ampere and the voltage at the track transformer is adjusted to 7 volts. The limiting impedance $Z_L = 4 \angle 83$ deg. ohms.

Line circuit current in the rails under the rear train is $0.87 \nwarrow 1$ deg. ampere as given in Table II. The drop away current in the rails at 90 deg. phase displacement is taken from Table III, $i = 0.111$ ampere.

Let $z = 0.25 \angle 60$ deg. loop impedance of rails per 1000 ft.

$g = 0.2$ conductance of ballast per 1000 ft.

$z_0 =$ surge-impedance of the track

and $\alpha =$ attenuation constant

Then

$$z_0 = \sqrt{z/g} = \sqrt{\frac{0.25 \angle 60^\circ}{0.2}} = 1.12 \angle 30^\circ \text{ ohms}$$

$$\alpha = \sqrt{zg} = \sqrt{0.25 \angle 60^\circ \times 0.2} = 0.224 \angle 30^\circ \text{ hyp.}$$

$$= 0.1935 + j\,0.112 = 0.1935 + j\,\underline{0.0713}$$

$$\theta = 2\,\alpha = 0.387 + j\,\underline{0.143}$$

and
$$\delta_A' = \tanh^{-1}\frac{Z_L}{z_0} = \tanh^{-1}\frac{4 \angle 83^\circ}{1.12 \angle 30^\circ}$$

$$= \tanh^{-1} 3.57 \angle 53^\circ$$

Referring to the Chart Atlas of Complex Hyperbolic Functions[3] Table $XII_A$, we find by inspection from the curves

$$\delta_A' = 0.16 + j\,\underline{0.857}$$

We also have $\theta_{AC} = 3\,\alpha = 0.58 + j\,\underline{0.214}$

and $\delta_C' = \delta_A' + \theta_{AC} = 0.74 + j\,\underline{1.071}$

Referring again to the Chart Atlas we may take out the following functions.

$\sinh\theta = 0.45 \angle 31^\circ\ 30'$ .......... from Table $X\text{–}XI_A$
$\tanh\theta = 0.43 \angle 27^\circ$ .............. from Table $XII_A$
$\cosh\delta_A' = 0.273 \angle 35^\circ$ ........... from Table $X\text{–}XI_A$
$\sinh\delta_C' = 1.283 \angle 94^\circ\ 20'$ ........ from Table $X\text{–}XI_A$
$\tanh\delta_C' = 1.54 \nwarrow 6^\circ\ 40'$ ......... from Table $XII_A$

Employing formulas in Appendix II for train $C$ at an intermediate position in the block.

$$Y = \frac{\cosh\delta_A'}{z_0^2 \sinh\delta_C' \sinh\theta}$$

$$= \frac{0.273 \angle 35^\circ}{1.254 \angle 60^\circ \times 1.283 \angle 94^\circ\ 20' \times 0.45 \angle 31^\circ\ 30'}$$

$$= 0.376 \nwarrow 150^\circ\ 50'$$

and
$$K = \frac{\tanh\delta_C' + \tanh\theta}{z_0 \tanh\delta_C' \tanh\theta}$$

$$= \frac{1.54 \nwarrow 6^\circ\ 40' + 0.43 \angle 27^\circ}{1.12\,L\,30^\circ \times 1.54 \nwarrow 6^\circ\ 40' \times 0.43 \angle 27^\circ}$$

$$= 2.58 \nwarrow 49^\circ\ 50' = 1.665 - j\,1.97$$

or
$$-K = -1.665 + j\,1.97$$

Whence

$y = 0.376 \qquad v = \nwarrow 150^\circ\ 50' \qquad v - \beta = \nwarrow 149^\circ\ 50'$

$$\frac{Ey}{i} \angle (v - \beta) = \frac{7 \times 0.376}{0.111} \nwarrow 149^\circ\ 50'$$

$$= 23.7 \nwarrow 149^\circ\ 50' = -20.5 - j\,11.95$$

we then have

$m = -20.5 \qquad n = -11.95 \qquad e = -1.665 \qquad f = 1.97$

$$G_C = e - \frac{n}{2} \pm \sqrt{\left(\frac{n}{2}\right)^2 - mf - f^2}$$

$$= -1.665 + 5.975 + \sqrt{5.975^2 + 40.4 - 3.88} = 12.83 \text{ mhos}$$

$R_C = 0.078$ ohms

$$\tan^{-1}\left(\frac{-f}{G_C - e}\right) = \tan^{-1}\left(\frac{-1.97}{14.49}\right) = \nwarrow 7^\circ\ 45'$$

$$\gamma = v - \tan^{-1}\left(\frac{-f}{G_C - e}\right) = \nwarrow 150^\circ\ 50' - \nwarrow 7^\circ\ 45'$$

$$= \nwarrow 143^\circ\ 5'$$

$$\phi = \beta - \gamma = \nwarrow 1^\circ - \nwarrow 143^\circ\ 5' = +142^\circ\ 5'$$

$$I_S = \frac{i}{\sin\phi} \angle \gamma = \frac{0.111}{0.615} \nwarrow 143^\circ\ 5' = 0.181 \nwarrow 143^\circ\ 5'$$

It may be seen that the above values of $R_C$ and $I_S$ are given in the second and fourth columns in Table IV.

# Electric Conduction in Hard Rubber, Pyrex,
## Fused and Crystalline Quartz

BY HUBERT H. RACE*
Associate, A. I. E. E.

***Synopsis.**—The study of physical and electrical characteristics of insulating materials is of growing importance to the electrical industry because of the ever increasing potentials employed in electric generating and distributing equipment. The particular problem presented in this paper is related to engineering practise because polarization and conduction both result in the conversion of electric energy into heat. This produces increased local and general heating, which may be contributing causes to the progressive deterioration and final breakdown of the insulation. The constant potential method explained in this paper provides a means for studying the inherent voltage-current-time relations which are masked in experiments using alternating applied potential.*

*Part of the material contained in this paper was presented by the writer to the faculty of the Graduate School of Cornell University for the degree of Doctor of Philosophy. The investigation was later continued with the joint support of the Hecksher Research Council and the General Electric Company.*

*Several methods were tried for obtaining conducting surfaces on the specimens for constant potential tests. An improved method was devised for making tests and experimental results on four materials were obtained. Peculiar reversals were observed in the charge and discharge curves for fused quartz.*

*The summary of experimental results is followed by suggestions for further research along similar lines.*

---

### APPARATUS AND PROCEDURE

### A. *New Method of Measurement.*

PREVIOUSLY the most precise measurements of the extremely small currents obtained in d-c. tests on good solid dielectrics have involved the use of a quadrant electrometer as a quantitative measuring instrument.

The erratic shifting of the zero point and changing of the sensitivity of an electrometer led the writer to devise a method of measurement which uses the electrometer as a null indicating device, so that changes in sensitivity do not affect the results. The method used is convenient and accurate for a range from $10^{-12}$ to $10^{-18}$ ampere, when the current is changing by only a very small percentage over a period of ten seconds or longer.

The object of the tests reported in this paper was to determine curves of electric current flow as functions of time through certain solid dielectrics after constant potential had either been applied to, or removed from, opposite faces of a flat plate of the sample.

The charge and current curves to be expected when constant potential is applied to such a sample are shown in Fig. 1. The great proportion of the charge is stored almost instantaneously, but because the dielectric is not perfect, the charge collected continues to increase. The curve of charge will approach a straight line whose slope will be zero if the final conductivity is zero, and will be finite if the final conductivity is not zero. The current curve is the first derivative of the charge curve and will have the general character shown. Its shape during the first instants will depend upon the characteristics of the external circuit.

The initial pulse of the current passes in a very small fraction of a second after applying the potential and was not measured in any of the reported tests. For some materials, the stored charge continues to increase for weeks after the potential is applied, and is kept constant. It is this long-time current that has been measured in these tests. When the potential is removed after a long-time charge, the currents are similar but reversed in direction.

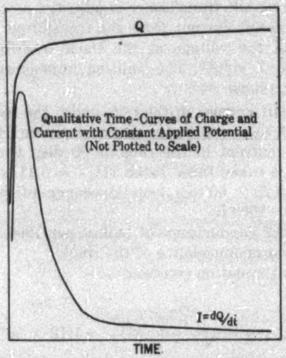

FIG. 1—QUALITATIVE CHARGES AND CURRENT CURVES

The currents obtained are smaller than can be measured with a galvanometer, so that a circuit using a sensitive electrometer was used. The diagram shown in Fig. 2 will help to explain the method of measurement. $C_s$ is the sample to be tested. $C_A$ is an auxiliary air condenser of known capacitance. $P$ is a potentiometer used to vary the potential applied to the lower plate of $C_A$. The quadrant electrometer, *Q. E.*, is used as a very sensitive electrostatic voltmeter to indicate any potential difference between the ground

*Presented at Northeastern District No. 1 Meeting of the A. I. E. E., New Haven, Conn., May 9-12, 1928.*

and the isolated system comprising the upper surface of the active area of $C_s$ and the upper plate of $C_A$.

Before applying potential to the lower plate of $C_s$, the upper system is grounded by closing the ground switch shown in Fig. 2. Then when potential is applied, the initial rush of current is conducted through this ground connection. If the ground connection is removed at any time while current is flowing through the specimen, the result will be an accumulation of charge on the isolated plates of $C_s$ and $C_A$, (upper system in Fig. 2). This will result in an increasing potential of the isolated system indicated by a movement of the electrometer spot of light.

Assume first that the electrometer is to be used quantitatively; then the motion of its spot of light should be recorded and interpreted in volts per second, which, when multiplied by the capacitance of the connected system, would give the current flow. However, the difficulties with this method are that the capacitance of the system is difficult to determine accurately, and the capacitance and sensitivity of the electrometer are not constant.

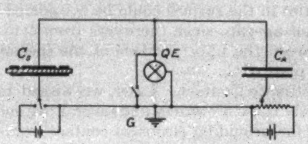

Fig. 2—Simplified Diagram of Connections

Now, as a different method, suppose that after the ground connection has been removed, the slider on $P$ is continually adjusted so as to keep the upper system (though insulated from ground) at ground potential. This is accomplished by so adjusting $P$ that the electrometer spot of light is kept at its zero position. Such an adjustment is possible because any electricity passing from $C_s$ can be drawn onto $C_A$ by properly varying the potential applied to the latter. If at the beginning and end of a certain length of time, the potential of the isolated system is at zero (or any other) potential, all of the current which has passed from $C_s$ in the interval will be collected on $C_A$. The average value of this current will be given by the equation:

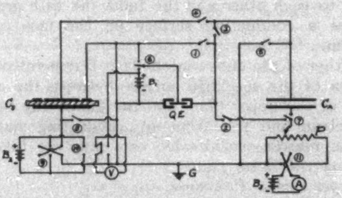

Fig. 3—Complete Diagram of Connections

$$i_{ave} = \frac{\Delta q}{\Delta t} = C_A \frac{\Delta e}{\Delta t} = C_A \left(\frac{e_2 - e_1}{t_2 - t_1}\right) \text{ amperes} \quad (1)$$

where $C_A$ is the capacitance in farads of the auxiliary air condenser and $(e_2 - e_1)$ is the change in potential applied to the lower plate of $C_A$ from $P$ during the interval of time $(t_2 - t_1)$, potential being measured in volts and time in seconds.

For all of the tests, the current was considered positive in the direction in which it was normally flowing while a positive potential was applied to the lower plate of $C_s$. To measure a positive current, it was necessary to apply a negative potential to the lower plate of $C_A$. When the current was reversed, for example during discharge after positive charge, the polarity of $P$ had to be reversed in order to keep the potential of the isolated system zero. During a reading, continuous observation of the electrometer scale was necessary; therefore, the set-up was so arranged that all switching was remotely controlled from the observer's position behind the scale.

The complete diagram of connections is shown in Fig. 3. The positions of all the switches for different conditions of test are given in Table I.

TABLE I
SWITCH POSITIONS FOR DIFFERENT EXPERIMENTAL CONDITIONS

| Switch number | Positions | | | Experimental conditions |
|---|---|---|---|---|
| | *A* | *B* | *C* | |
| 1 | open | closed | open | *A* = Before starting a run and during discharge readings. |
| 2 | open | open | open | |
| 3 | closed | closed | closed | *B* = At very beginning of a run and between charge readings. |
| 4 | closed | closed | closed | |
| 5 | open | open | open | *C* = During readings for charge curve. |
| 6 | down | down | down | |
| 7 | up | up | up | |
| 8 | closed | open | open | |
| 9 | open | right | right | |
| 10 | open | open | open | |
| 11 | down | down | down | |

The elaborate switching system shown in Fig. 3 is not necessary for simple current measurements, but was installed for flexibility in the use of the same equipment for other related tests.

*B. Apparatus.*

$C_s$ is a guard-ring condenser arranged to provide a uniform dielectric field between the parallel surfaces of the specimen and to allow the measurement of the current passing to the middle plate. It is mounted so that potential can be applied to the lower plate.

*Q. E.* is a Compton quadrant electrometer with a platinum sputtered quartz fiber. A potential of about 60 volts has been maintained on the needle for several months. The adjustment is such as to give a sensitivity of from 3000 to 4500 mm./volt, the scale being mounted at two meters. Sensitivities as high as 15,000 mm./volt were obtained but they were accompanied by rather unstable conditions with large shifts of the electrometer zero and were therefore not used. The instrument is shielded from air currents and the case is permanently grounded.

$C_A$ is an air condenser of known capacitance. A 64 by $10^{-12}$ farad fixed condenser having long quartz rods supporting and insulating one set of plates was used for measurement of the smallest currents. A variable parallel-plate air condenser, having a range in capacitance from 76 by $10^{-12}$ to 5360 by $10^{-12}$ farad, was used for measurement of larger currents. For these experiments, this capacitance was used at only three settings, namely, 5360, 1000, and 100. The rotating set of plates was mounted on amber bushings so as to eliminate leakage currents so far as possible.

$P$ is a Queen-Gray potentiometer carrying a normal current of 0.002 ampere with a potential range from zero to 1.91 volts, the smallest graduated division being 0.00001 volt. For large current readings, the potentiometer current was increased ten times, thus multiplying the potential readings by ten.

$A$ is a milliammeter for roughly measuring the current in $P$. Final adjustments were made by checking against a standard cell. The potentiometer current was kept flowing continuously, so as to maintain constant temperature, and therefore constant resistance, in the coils.

$V$ is a voltmeter for measuring either the potential to be applied to the specimen or that on the electrometer needle.

$G$ is the common grounding point for the entire system.

$B_1$ supplies constant potential to the electrometer needle.

$B_2$ is a battery of over 800 volts for supplying any desired potential to $C_s$.

$B_3$ is a 24-volt storage battery supplying the continuous current in $P$.

C. *Preparation of Specimens.*

With Air-Gap. The first series of experiments was made with specimens having polished plane parallel surfaces placed between the plates of a standard air condenser. The upper plate consists of two parts, the center section and a guard-ring. The guard-ring is supported on amber bushings which insulate it from the lower plate. The height of these bushings may be adjusted to give any desired spacing between the plates up to about an inch. The center section is supported from a brass cross-bar which is insulated from the guard-ring by a pair of sulphur bushings. The guard-ring was permanently grounded and the center section, although isolated from ground during a reading, was maintained at ground potential. (See method of making measurements.) Thus, a uniform electric field was maintained in the specimen out to the edge of the guard-ring and fringing was eliminated at the edge of the center section on which measurements were made.

A copper wire, supporting one of the glass mercury cups, was mounted on the isolated center section of the upper plate. A mechanical lever arrangement was provided so that the entire condenser could be rocked, thus moving the mercury cup up and down. An amalgamated copper wire suspended directly from the electrometer quadrants was adjusted to dip in this mercury cup when the latter was in its up position, but to be several millimeters above the surface of the mercury when the cup was down. Thus the connection between $C_s$ and $Q.\ E.$ could easily be made or broken, being remotely controlled from the observer's position behind the electrometer scale.

In the piece of apparatus just described, no attempt was made to provide good electrical contact between the lower surface of the specimen and the brass plate upon which it rested. A small air-gap here due to irregularities in the surface could be considered as part of the total air-gap, since there was from 1 to 2 mm. space between the upper surface of the specimen and the upper plate of $C_s$.

With Intimate Contact. Later, we wished to eliminate entirely these air spaces and several methods were suggested for providing electrical contact between the condenser plates and the surfaces of the specimen. We were prejudiced against the use of mercury contacts by the difficulty of making a suitable guard-ring arrangement, and also by the work of J. E. Shrader[9], who concluded from his experiments that powdered graphite provides better contact than mercury, especially on polished surfaces. We finally decided on two methods of making these contacts: (a) by depositing a metal film on the surface, either by silvering or by sputtering in vacuum, or (b), by painting both the specimen and condenser plate surfaces with India ink in which we had mixed very finely powdered graphite and sticking them together while wet. When dry, they adhere to each other and the India ink with graphite provides a conducting surface on the face of the specimen.

In either of the above methods, it is imperative that the area of the specimen surface between the center section of the upper plate and the guard-ring be perfectly clean and free from any conducting material. For this reason, considerable care must be taken in mounting the brass plates.

D. *Experimental Procedure.*

Detailed Procedure. Before starting a run, to insure that the specimen had no residual polarization, the switches were thrown as shown under $A$, Table I, Under this condition, $C_s$, $Q.\ E.$, and $C_A$ were connected together and isolated from the rest of the set-up, all of which was grounded. If the specimen had any residual polarization, the electrometer would show a drift in one direction or the other; but if the sample were completely depolarized, there would be no electrometer drift, in which case the specimen was ready for test. If the electrometer showed a drift, both plates of the condenser containing the specimen were grounded and left until the residual polarization became zero.

Before starting the experiment, it was also necessary to adjust the potential of $B_2$ to exactly the value required to give the desired potential gradient in the specimen. The voltmeter $V$ was used in making this adjustment.

For aid in describing the exact method of procedure, let us consider the sample data sheet shown in Table II.

At exactly 8:00 p. m., potential was applied to the specimen by throwing switch 9 to the right, switch 1 having been previously closed and switch 8 opened. The charging current was then passing through switch 1 to ground without being measured. The position of all switches is shown in column B, Table I.

*Estimated.

Exactly 45 sec. later, switch 1 was opened and $P$ was continuously adjusted so as to keep the electrometer spot of light approximately at its zero position. $P$ was carefully adjusted so that the electrometer spot was *exactly* on its estimated zero position at 8:01:15, after which, switch 1 was again closed and the reading of $P$ recorded. The potentiometer slider was then set back to zero ready for the next reading. This process was repeated whenever it was desired to take a reading. At the end of each reading, in fact 30 sec. after closing switch 1, the true position of the electrometer zero was read. If this differed from the estimated position, the reading was corrected for the error, the electrometer calibration having been previously determined. The readings came in rapid succession, at least for the first few hours, after which they could be taken at longer intervals.

Eliminating Switching Errors. The electrometer zero position was not stationary, but was continually shifting. Therefore it seemed necessary, especially for readings of 10 min. duration, to provide a switching arrangement so that the electrometer zero could be accurately determined just before the final adjustment was made at the end of a reading. For this purpose, a mercury cup was provided, into which an amalgamated copper wire could be made to dip. (Switch 3.) When it was desired to determine the electrometer zero without grounding the combination of $C_s$ and $C_A$, switch 3 was opened, switch 1 closed, and the zero position read on the scale. Then switch 1 was opened, switch 3 closed, and the final adjustment of $P$ made to bring the spot of light to its zero position.

There were two possible sources of error in this process.

a. If, when switch 3 was opened, the isolated system was not at ground potential, a certain amount of electricity was removed from the system when the electrometer was grounded. For readings at the very end of a discharge curve, this quantity might be an appreciable proportion of the total charge collected during the 10-min. period.

b. The second source of error was probably the greater, however. It seemed impossible to keep the mercury sufficiently clean to eliminate a contact e. m. f., which was generated every time a switch was opened or closed. It was suggested that a layer of oil might be placed on the mercury to eliminate oxidation and thus prevent this e. m. f. This was not tried, however, because the method already described was devised for taking the data without making any switching operations during a reading.

Minimizing Leakage Errors. The value of current to be measured was so small that extra precautions had to be taken to make sure that electricity did not leak on to the system from some outside source, or that current which we wished to measure, did not leak off without being measured. For these reasons, the entire outfit was surrounded with a permanently grounded electrostatic shield. Also, the set-up was so designed that the isolated system, comprising the upper plate of $C_s$, the electrometer quadrants and one set of plates of $C_A$, was supported entirely by these three pieces of apparatus. Thus, the four chances for leakage from this system were:

1. Surface leakage from the upper plate of $C_s$ to the guard ring;

2. Surface leakage from the free quadrants of *Q. E.* to its case;

3. Surface leakage over the insulating supports, from one set of plates to the other of $C_A$;

4. Conduction through the air due to ionization.

To guard against the first, the surface of the hard rubber was carefully scraped before the guard-ring and upper plate were mounted, the surfaces of the glasses were cleaned with concentrated nitric acid, washed with ammonium hydroxide, and then with distilled water.

The second possibility offers very little chance for leakage since the quadrants were mounted on amber, the surface of which had been highly polished and carefully cleaned.

The third offers a greater chance for leakage. The larger condenser $C_A$ is of the multiple-plate type manufactured for precision radio work. The insulation furnished by the manufacturer was a pressed mica composition. This was found to have relatively large surface leakage and was replaced by Bakelite strips having amber bushings. Even with these precautions, it was found that the combination of the electrometer with $C_A$, $C_s$ being disconnected, showed a leakage drift always in the same direction but varying erratically from 2 by $10^{-15}$ to 10 by $10^{-15}$ amperes. In an attempt to decrease this leakage when reading small currents, a small fixed air condenser was made with one set of plates insulated and supported by long quartz rods. The system leak was thereby reduced to about one-third the previous value.

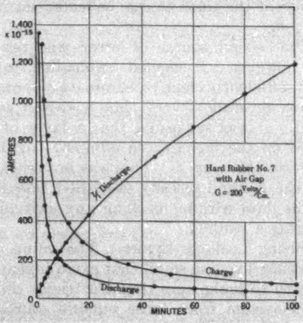

Fig. 4—Hard Rubber No. 7 With Air-Gap

The fact that the observed leakage was always in the same direction leads us to think that some at least was due to the fourth possibility mentioned above, especially in $C_A$ where the air path between plates was relatively short and of large area.

J. J. Thomson[13], in his book "The Conductivity of Electricity Through Gases", quotes C. T. R. Wilson, who, in 1901, showed that in dust-free air, the maximum quantity of electricity which can escape in one second from a charged body in a closed space whose volume is $V$ cu. cm. is about $10^{-8}\ V$ electrostatic units. This equals about 0.333 by $10^{-17}\ V$ coulombs per sec., and is sufficient to account for part, but probably not all, of the leakage observed in our experiments.

Null Method Eliminates Electrometer Errors. The errors that make it inconvenient to use an electrometer as a deflection instrument will be summarized briefly.

It is difficult to determine accurately the capacitance of $C_s$ or the electrometer, and both of these must be known if the deflections are to be interpreted in amperes. The electrometer capacitance changes with any change in the position of the needle. The fast readings are in error because of the inertia of the moving needle and the viscosity of the air surrounding it. More serious than any of these, perhaps, is the fact that the calibration changes with variations of the zero position and other factors; and also that there is not a straight line relation between deflection and the potential on the quadrant.

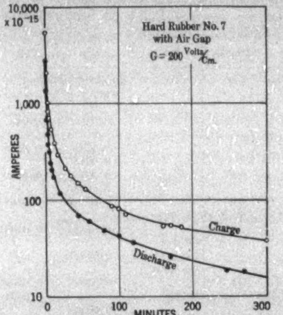

Fig. 5—Hard Rubber No. 7 With Air-Gap

For all of these reasons, while an electrometer is very useful in making relative measurements, it has disadvantages when used as a quantitative instrument. Therefore, the simpler quantitative method already described was devised, using the electrometer only as a very sensitive zero potential indicator.

## Experimental Results

### A. *With Air-Gap.*

As already indicated, the first tests were made with the gap between the upper surface of the specimen and the upper plate of the condenser. A plate of hard rubber and one of Pyrex glass were tested in this way.

In Fig. 4, curve 1 shows the charge curve which although not plotted, was continued for nearly 4000 min., or until the current had decreased to about 15 by $10^{-15}$ amperes. Curve 2 shows the discharge taken after the charge by removing the potential and grounding the lower plate.

Fig. 4 is shown for two reasons: first, to illustrate how rapidly the current drops during the first part of the discharge curve, and yet how long, relatively, it takes for this current to die out entirely. The second reason is embodied in curve 3, in which the reciprocals of the points on curve 2 have been plotted against time. If curve 2 were an hyperbola with the axes for asymptotes, curve 3 would be a straight line passing through the origin. The plot shows very definitely that curve 2 is not a hyperbola.

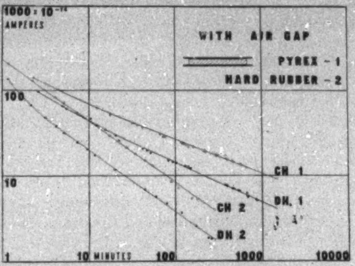

Fig. 6—Hard Rubber No. 7 and Pyrex with Air-Gap

The wide difference between curve 1 and 2 is due to the air-gap, for eliminating the gap eliminated the difference, except for the actual conduction current which is, of course, absent on discharge, (see Figs. 7 and 8). For this reason, subsequent tests were made with intimate contact between the specimen and upper plate of $C_s$.

Fig. 5 shows that the relation between $i$ and $t$ does not even approximately follow a simple exponential law.

The charge and discharge curves for hard rubber, which have been shown in the last two figures plotted in different ways, are plotted in Fig. 6 using logarithmic scales for both current and time ($C\,H - 2$ and $D\,H - 2$). It is seen that the experimental data give practically a straight line relationship between log. $i$ and log. $t$.

$C\,H - 1$ and $D\,H - 1$ are similar charge and discharge curves taken for a sample of Pyrex glass, nearly 15 cm. thick. The principal fact to be gained from these is that the straight relationship makes the polarization an inverse power function of the time:

$$i_p = (\text{const})\ t^{-b} \qquad (2)$$

*B. With Intimate Contact.*

Pyrex Glass. After the curves and $C\,H - 1$ and $D\,H - 1$, shown in Fig. 6, had been obtained, the same specimen was prepared with intimate contact between the surfaces of the specimen and the plates of the condenser. The results of this latter test, plotted in a similar manner, are shown in Fig. 7.

The upper series of circles, through which no line is drawn, are points on the charge curve which is approaching a horizontal asymptote, the final conduction current $I_g$. In the case of Pyrex, $I_g$ is a very appreciable proportion of the charge current.

The series of completely filled dots gives the observed discharge curve, which follows the straight-line law for over 100 min., after which it drops off more rapidly.

The series of half filled circles is obtained by subtracting the value $I_g$ from each of the charge readings, obtaining thereby the effect of polarization alone. These lie superimposed upon the points of the discharge curve showing that the phenomenon is reversible. This relationship may be expressed by the equation:

$$i_p = i\ (\text{charge}) - I_g = -\ i\ (\text{discharge}) \qquad (3)$$

This relation was stated long ago by Curie[1] as a result of the law of superposition.

Although charge curves similar to Fig. 7 are not shown in his published work, the relation represented by eq. (2) was reported by von Schweidler,[10] who obtained discharge curves, similar to those shown in Fig. 7, for mica, paraffin paper, and glass condensers.

A curve for fused quartz obeying the law of eq. (2), was shown by A. Jaquerod and H. Mugeli;[6] but they, like von Schweidler, chose to convert this simple experimentally observed relation to a sum of exponential terms, believing this form easier of theoretical explanation.

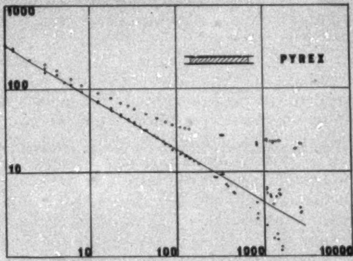

Fig. 7—Pyrex with Intimate Contact

The deviation of observed points in Fig. 7 from the straight-line law may be due to one or both of two causes.

*a.* A slightly erratic unidirectional instrument leak, comparable to the lower values of the curve, was observed. This error decreased the discharge readings but added to the charge readings, the charge current being in the opposite direction to the discharge. The error might well account for the observed departures for the points of $i_{CH} - I_g$ lie above the line and the discharge points lie below it.

*b.* The other possible explanation is that the reaction of the material actually does not obey the law. This can be determined only by further experiment using more refined methods so as to eliminate possible apparatus errors.

Hard Rubber. Fig. 8 shows the results of a series of experiments on two samples of hard rubber. Specimen 7 was tested at four different potential gradients, giving curves 1, 2, 3, and 4. Specimen 5, obtained from a different manufacturer, was tested at only one potential gradient as shown by curve 5. Curves 1, 3, and 4 were taken with a positive potential applied to the lower plate of the condenser. A poor switch contact destroyed the value of the discharge readings for curve 1, so that they were not plotted. Curve 2 was taken with a negative potential applied to the lower plate of the condenser. This shows that the results were independent of the direction of the applied potential.

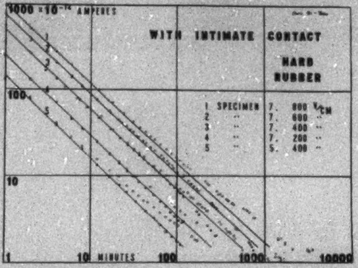

Fig. 8—Hard Rubber No. 5 and No. 7 with Intimate Contact

The unidirectional apparatus errors were found by several tests to be comparable to the value of the final conduction current for hard rubber. In runs 1, 3, and 4, these errors were in the same direction as the final conduction current and therefore add up to give the observed constant value $I_g$. In run 2, the apparatus errors were in the opposite direction to the conduction current, and therefore lowered the charge and raised the discharge curve. Indeed it seems that the errors and the conduction current are about of the same magnitude, for the charge and discharge curves are nearly superimposed. This suggests a way of canceling out the errors, if it is found impossible to remove their cause; namely, to take two runs at each potential gradient under identical conditions, except that the direction of the potential is reversed.

Because the experimental data indicated that the curves were directly proportional to the applied potential, the lines 1, 2, 3, and 4, were so drawn. They are plotted parallel and apart by distances, so that the ordinates of current at any instant are directly proportional to the applied potential gradient. By observing the agreement of the lines with the observed points, the reader may draw his own conclusions regarding this proportionality.

Curve 5 shows that specimen 5, while having approximately the same time rate of change of polarization as specimen 7, gives less than one-third as much polarization under the same conditions. The composition of these two samples is not known to the writer, so no deduction can be made as to the reason for this difference.

The values of $I_g$, taken at the end of each charge curve, included the apparatus errors in the same direction as the actual conduction current. Therefore, the best we can say is that the actual conduction current was equal to, or less than, the observed value; and that the actual apparent resistivity of the material was equal to or greater than that computed using the observed values of $I_g$. (See Table IV.)

Fused Quartz. A sample of fused quartz and one of crystalline quartz on which some previous measurements had been made were obtained from the Bureau of Standards. The writer believes that these are the same samples used by V. E. Whitman[16] in making similar studies on current flow in fused and crystalline quartz. The fused quartz was in the shape of a thin disk with plane parallel faces. It was silver-plated on both sides, with a suitable guard-ring.

Fig. 9 shows a typical example of some of the first measurements made on this sample. No measurements were taken within the first minute after applying or removing the potential and it is impossible to show exactly what was happening at the two extremes of either curve since in this figure they were plotted to uniform scales.

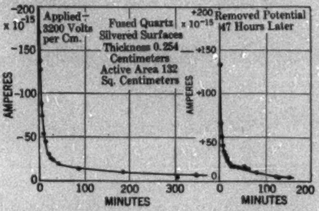

Fig. 9—Fused Quartz with Silvered Surfaces

Several sets of data with different applied potentials were taken with the hope of finding the relation previously shown for hard rubber in Fig. 8. No such relation was found; on the contrary, it was impossible to get the same curve twice with the same applied potential. Also curves obtained with positive applied potential, while of the same form, were not symmetrical with those obtained with a negative applied potential. In fact, the current-time curves for this sample did not seem to obey any quantitative law, but seemed rather to be unaccountably erratic.

It might be well to state here that the upper plate of

$C_s$ (see Figs. 2 and 3) was connected to ground all of the time except while a reading was actually being taken; even then, it was kept at ground potential. Each time before potential was applied the sample was tested to be sure that there was no residual current flowing due to relaxation from some previous charge.

The investigator was gradually convinced that something unexpected, and which he was not observing, was happening during the first minute. Up to this time the first reading for each curve had been taken one min. after applying or removing the potential. Thereafter, the electrometer was used quantitatively, and as many readings as possible obtained during the first minute.

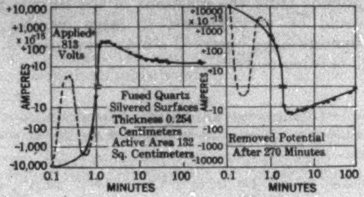

FIG. 10—FUSED QUARTZ WITH SILVERED SURFACES

Fig. 10 represents a typical set of results, the heavy line showing how they were first interpreted. These points give no indication of the current flow between the relatively short observations; and subsequent curves indicated that the data should be interpreted as slow oscillations shown by the dotted curve.

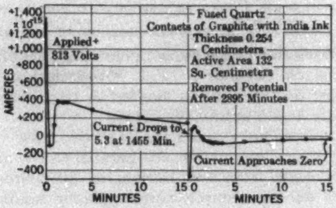

FIG. 11—FUSED QUARTZ WITH GRAPHITE CONTACTS

At first it was suspected that this reversal might be caused by some peculiar condition of resonance in the circuit. This idea was discarded because when an air core inductance of about 400 millihenrys was connected in series with $C_s$, no apparent change was noticed in the charge and discharge curves. Computations also showed that impossible values of circuit constants would be necessary to give a frequency of natural oscillation as low as one cycle per min. Therefore it was concluded that these reversals were either due to the contact surfaces, or else were a characteristic of the material itself.

The next step was to try new contact surfaces. The silver film was removed from the quartz plate, the surfaces were carefully cleaned, and new contacts provided by painting with India ink containing finely powdered graphite. The first coat was allowed to dry; then a brass disk was painted with the same mixture and placed on the coated surface, thus insuring good contact, since the brass was held firmly after the ink had dried.

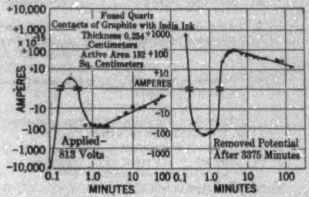

FIG. 12—FUSED QUARTZ WITH GRAPHITE CONTACTS

Figs. 11, 12, and 13 show typical sets of data taken with the new contacts. The reversals are shown very clearly. The relative magnitudes of the first and subsequent readings for each run are indicated best by Fig. 11, which is plotted using uniform scales. The same set of data is plotted for a much longer time in Fig. 12, using logarithmic scales. The effect of applying a negative instead of positive potential to $C_s$ is shown in Fig. 13.

In Figs. 12 and 13 the curves are broken where they cross the axis because the scales are logarithmic and no zero can be shown. So far as we could see, changing the contact surfaces did not affect the results, so that they indicate the reactions of the material itself. It is quite possible that in each case the observed results were preceded by unmeasured oscillations of much shorter period. As an aid in the possible interpretation of these results, the complete history of this sample of fused quartz, for two months preceding the final experiments, is tabulated in Table III.

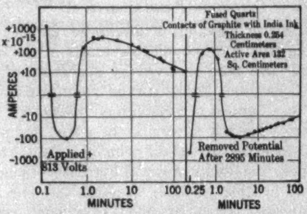

FIG. 13—FUSED QUARTZ WITH GRAPHITE CONTACTS

TABLE III

HISTORY OF PLATE OF FUSED QUARTZ

Previous to the tests recorded below the plate, with silvered surfaces connected together had been lying idle for some time. No residual charge could be detected

| Date | Days after 11/20 | Treatment | Remarks |
|---|---|---|---|
| 11/20/27 | 0 | Applied − 813 volts | Data plotted Fig. 9 |

*Reversals of Current in Fused Quartz.*

Reversals in direction of discharge current curves occurring after corresponding reversals of the charging potential have been observed by numerous investigators.[6] Richardson[8] shows curves demonstrating this effect for a sample of crystalline quartz cut parallel to the axis. The law governing the effect was stated in 1889 by Jacques Curie[1] as the principle of superposition.

However, the results shown in Fig. 10 to 13 cannot be explained by this principle because the specimen is kept grounded (short-circuited) after each test until it has relaxed as completely as it will; *i. e.*, until the upper plate shows no tendency to acquire a charge in either direction if the ground connection is removed. This is assumed to indicate a neutral or unstressed condition in the dielectric. Then, according to the principle of superposition, if a positive potential of constant magnitude were applied, the current flow would always be in the positive direction.

Perhaps, upon depolarization, the polarizing elements do not regain truly neutral positions, although they do assume an arrangement which is in stable equilibrium. Thus, the reversals observed might be caused by overstraining and slow time oscillation about a new equilibrium arrangement whenever the applied potential is changed.

This effect might be accounted for by the condition assumed at the point (6) of Fig. 12 in the recent paper published by Malti[7].

The writer is not prepared to offer any other explanation of the results observed, although he believes them to represent truly the reactions of the sample tested. He would be very pleased to learn whether other investigators have observed similar reactions on fused quartz or other materials.

TABLE IV

SUMMARY OF EXPERIMENTAL RESULTS

All data were taken at temperature of 20 deg.–22 deg. cent.

Column 1—material under test

Column 2—$G$ = applied potential gradient in volts/cm.

Column 3—$\rho_a = \frac{e}{i_1}$ = apparent resistivity where $i_1$ is the current per unit area in amperes/sq. cm. measured 1 min. after the application of potential

Column 4—$\rho_f = \frac{e}{i_g}$ where $i_1$ was the final constant value of $i$

Column 5—ratio of $\rho_a/\rho_f$

Column 6—coefficient $b$, when the polarization current is exressed by equation (1).

A compilation of the known characteristics of silica is presented by Sosman[12], "The Properties of Silica." However, no information similar to that observed by the writer was found in this work.

Crystalline Quartz cut Parallel to the Axis. A plate of clear crystalline quartz, cut parallel to the axis, was also borrowed from the Bureau of Standards. The contacts on this sample were made by sputtering a gold film in vacuum on the carefully cleaned surfaces. Here, again, a guard-ring was provided. The chief objection to this type of contact is the length of time necessary to get a good conducting film.

Fig. 14 shows the only set of data obtained to date on this sample. The upper curve shows that the final steady current is very high compared to that of fused quartz. The lower curve shows a return polarization current larger than the charging current for the first minute and a half, and continuing for an extremely long time. In fact, one month after the potential was removed, a discharge current could still be detected, although the plates had been short-circuited for the entire time. This indicates the difficulty of obtaining complete relaxation in such a material. The writer believes that if the charging current had been continued for 100,000 min., the lower part of the discharge curve might have continued a straight line instead of falling off as it did.

## SUGGESTIONS FOR FURTHER RESEARCH

### A. *Studies Similar to Those Reported Here.*

1. Studies on a large number of materials to separate them into the following three groups; (a) those showing both polarization and conduction; (b) those showing appreciable polarization and negligible conduction; (c) those showing negligible polarization and appreciable conduction.

For these studies, it would be necessary to keep constant the parameters listed below; but this would not require the apparatus necessary to vary them through wide limits, and therefore could be done much more easily.

2. Intensive study on a representative substance from each of the three groups listed above. To accomplish such a study, it would be necessary to control all of the variables which affect the phenomena. Then, by varying one at a time, keeping all the others constant, the individual effects of each parameter could be studied. This would be a large undertaking, require especially designed apparatus, and take a great deal of time. However, we cannot say much regarding dielectric reactions until it is accomplished. The possible parameters are: (a) thickness of specimen; (b) area of specimen; (c) temperature; (d) humidity; (e) potential gradient; (f) length of time of application of potential.

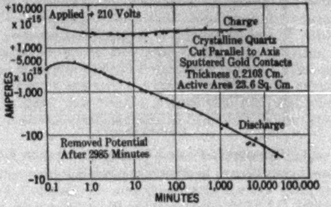

FIG. 14—CRYSTALLINE QUARTZ WITH GOLD CONTACTS

From this study a classification would be obtained separating dielectrics into two groups: (a) those whose reactions obey laws of proportionality with the possible parameters, and whose reactions can therefore be computed; (b) those whose reactions are quantitatively erratic and non-predictable.

### B. *Studies of Polarization Potential.*

The author believes that very interesting current-time relations will be found if, after a complete charge curve, the potential is reduced, not to zero as in the case of all the tests reported in this paper, but to a potential smaller than that previously applied and in the same direction. A family of such curves could be obtained by having identical charging conditions, and reducing the potential to different values, ranging from zero up to the potential applied during charge, (see Reference 8).

### C. *Studies of Residual Charge.*

If, after a complete charge curve, the condenser is short-circuited and then isolated, a difference of potential will gradually appear between the plates, showing that a free charge is collected on them which may be removed by again short-circuiting the plates. It would be very interesting to study this liberation of residual charge:

1. As a function of the time allowed between successive short circuits;

2. As a function of the rate of rise of potential which could be controlled by varying the capacitance of an air condenser placed in parallel with the specimen.

### D. *Studies of Energy Involved.*

1. Input Energy.

This may be computed by the equation

$$W_{input} = E_{CH} \int_0^d i_{CH}\, d\, t \qquad (4)$$

where $d$ is the time at which the charge is discontinued.

2. Recoverable Energy.

If experiments are performed as indicated under section $B$, above, and the value of the reduced potential $E_{DH}$ is such that current flows against this potential, the energy recovered is given by the equation:

$$W_{recovered} = E_{DH} \int_0^f i_{DH}\, d\, t \qquad (5)$$

where $f$ is the instant of time at which $i_{DH}$ reverses and begins to flow in the same direction as the previous charge current.

3. Loss to Heat.

The difference between the energy input and the energy recovered is energy lost. In all the experiments reported in this paper, the energy recovered was zero, since both plates of the condenser were maintained at zero potential during discharge. Therefore, all the energy input was lost to heat; (a), in forcing the material through the cycle of polarization, and (b), in the actual $I_o^2\, r$ loss. Therefore, the energy used in polarization could be computed by substracting from the input energy, the energy recovered, and the $I_o^2\, r$ loss, if we could assume that $I$ final $= I_o$.

### E. *Correlation of A-C. and D-C. Tests.*

As the frequency of the alternating potential is decreased, the loss per cycle ought to approach the loss per cycle of a d-c. test having the same magnitude of applied potential. Therefore, very interesting data should be obtained by using the same sample for both types of experiment and comparing the results.

## SUMMARY

A. A simple, sensitive modification of previous methods is developed for measuring current-time, charge and discharge curves in solid dielectrics with constant applied potential.

B. Coefficients of final apparent resistivity agree very well with those reported by earlier investigators. The fact that a higher value is reported for fused quartz is due to the extreme length of time taken, to allow the current to decrease to its minimum, and to the high sensitivity of the method of measurement.

C. The phenomenon studied must be due to some form of polarization, since representative curves were obtained with an insulating air-gap between the specimen and the upper plate of $C_s$.

D. 1. For all the materials studied, the law expressed by equation (**2**) is verified over a considerable length of time. An exception was found in fused quartz during the first minute or so after changing the applied potential.

2. The law expressed by equation (**3**) is verified for Pyrex glass and hard rubber.

3. For hard rubber within the range of potential studied, we have found that the polarization current is directly proportional to the applied potential, and that the relaxation coefficient $b$ in eq. (**2**) is independent of the applied potential.

4. The sample of fused quartz behaved differently from the other materials tested, and showed current reversals unaccounted for by the principle of superposition. Its reactions cannot be taken as representative of all dielectrics.

E. The final apparent resistivity of some materials can be determined only after a constant potential has been applied for several days; *i. e.*, it takes days, and even weeks, for $i_p$ to become negligible compared to $I_g$.

F. Of the several methods tried, India ink with finely powdered graphite was found to give the most satisfactory contact between the surfaces of the specimen and the brass plates of $C_s$.

### GENERAL CONCLUSIONS

A. Solid dielectrics showing the property of polarization may be found to divide themselves into distinct groups having entirely different conduction characteristics.

B. The mechanism of conduction in dielectrics differs from that in metals so that the expression "dielectric resistance" has an entirely different physical meaning from the expression "metallic resistance."

C. The present need in this field is for thoroughly coordinated, carefully executed researches to determine how *all* the related phenomena vary with changes of *all* the parameters which affect them.

## Discussion

**C. L. Dawes:** I am particularly interested in work which involves the properties of dielectrics, since at Harvard University we are and have been for some time past conducting a similar study. In fact, P. L. Humphries, an instructor in Electrical Engineering, has already obtained the dielectric characteristics of Pyrex glass over a wide range of frequencies and temperatures. These results will be published in the *Electrical World* in the near future. Our special problem at present is the study of the ionization of gases. We restrict the energy flow to the gas with a slab of Pyrex glass, having an effective electrode area of 111.3 sq. cm. and a thickness of 1.411 cm. The characteristics of the gas are obtained by deducting the characteristics of the Pyrex glass from the measured characteristics of the glass and gas in series. It is, therefore, necessary to know the characteristics of the Pyrex glass. We first used ordinary plate glass, but later found Pyrex glass more suitable, because its characteristics vary much less with change in temperature. We attempted, without success, to obtain a suitable piece of fused quartz for this work.

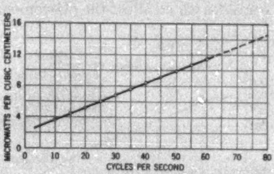

FIG. 1—FREQUENCY-POWER CHARACTERISTIC OF PYREX

3450 volts per cu. cm. gradient. Temperature—25 deg. cent.

In Fig. 1 herewith is shown a plot which gives the power loss of Pyrex glass as a function of frequency. The curve was obtained at 25 deg. cent. and with 5000 volts r. m. s. impressed, giving a gradient of 3540 volts per cm. The relation of power loss to frequency is linear. If the curve is extrapolated to zero frequency, the corresponding loss is 1.4 microwatts per cu. cm. This corresponds to $4.47 \times 10^{-9}$ watt per cu. cm. if the voltage gradient is 200 volts per cm. The watts loss per cu. cm. obtained by Professor Race with a gradient of 200 volts per cm. and at the final constant value of direct current may be obtained from Table IV and is equal to $(200)^2/(8.6 \times 10^{-16}) = 4.65 \times 10^{-13}$ watt. It is thus seen that there is a great difference between these two values. It does not seem possible that this difference can be accounted for by differences in the specimens tested.

It would have added considerably to our knowledge of dielectrics if it had been possible for us to obtain data between 20 cycles per second and zero frequency, and thus attempt to explain the above discrepancy. Addenbrooke[1] has made some comparisons of the d-c. characteristics of dielectrics with their a-c. characteristics. However, in our present research we are not particularly concerned with the Pyrex glass itself, but rather in the application of its dielectric characteristics to another problem. Hence, at this time we do not feel justified in carrying the research any further in this particular direction.

At first sight, it seems an anomaly that in the measurement of power loss, we are able to obtain far greater sensitivity with alternating current than with direct current, in spite of the fact that with alternating current, the energy component of the current is associated with a quadrature component having many times the value of the energy component. These two components must be separated in the power measurement. The reason that this high sensitivity is obtained with alternating current is that we are able to employ a very sensitive tuned galvanometer, working in conjunction with a vacuum-tube amplifier. Although we have an extremely sensitive d-c. galvanometer ($10^{-11}$ ampere for 1 mm. deflection at a distance of one meter) its sensitivity would need to be increased 1000 times to adapt it to the measurements of these samples of high-resistivity materials. Hence, some indirect method, such as is described in Professor Race's paper, is usually necessary Heretofore, very small currents such as electronic saturation currents, have been determined by measuring the change of potential across a condenser with some type of electrostatic instrument, often a gold-leaf electroscope. Professor Race eliminates the deflection errors, which are large in this type of instrument, by means of an electrostatic Poggendorff method. The instrument acts merely as a zero detector. From my own experience with this type of measurement, I agree with him that this null method has much greater inherent precision than the deflection method.

It is interesting to note that d- and a-c. losses in cables have been compared by Percy Dunsheath of the Henley Telegraph Works of England. He has found that for the same voltage gradient, the a-c. loss at 50 cycles varies from 13.4 to 3460 times the d-c. loss, depending on the temperature. ("Dielectric Problems in High-voltage Cables;" *Journal I. E. E.*, Vol. 64, 1925-26, page 113). At Harvard University we are making similar studies with cables and plan to publish some of the results.

We all realize that our present knowledge of the behavior of dielectrics is rather vague. The Committee on Dielectrics of the National Research Council and various committees of the national engineering societies are working to avoid unnecessary duplication in dielectric research and to correlate the results. The results of this paper, when correlated with similar work being carried on elsewhere in this country, should add to our knowledge of the behavior of dielectrics under the action of direct current.

**F. W. Grover:** I have been much interested in the paper by Professor Race because he deals with a subject on which I did some experimental work while at the Bureau of Standards. We studied what is called the absorbed charge of a condenser, that is, the charge that comes out of a condenser after it has been discharged and short-circuited for a while. In this study it seemed almost impossible ever to discharge a condenser. This is true of the best mica condensers which we used for standards at that time. In fact you might say that the condenser acted like a continuous, perennial source of energy.

But the thing that has interested me especially in the work of Professor Race is that a supposedly homogeneous substance like fused quartz should show this effect. That theory of dielectric absorption which has received the most attention and which has been regarded by most observers as offering an explanation for the *qualitative* phenomena, although perhaps not for the *quantitative*, is the law of stratified dielectric, brought out by Maxwell. According to that, it is a necessity with inhomogeneity of the dielectric that absorbed charges appear at the surfaces where the layers meet. But according to Professor Race a homogeneous substance also shows absorption. Some of the earlier investigators claimed that with substances believed to be perfectly homogeneous they found no absorption at all.

One observer, some ten years ago, working with thin layers of paraffine, claimed that if precautions were taken to insure the exclusion of air films, no absorption was found in this case also. The results obtained by Professor Race on fused quartz, on the contrary, although obtained with no chance for the presence of air films, show a well defined absorption effect.

I think this work is very instructive from the standpoint of dielectric theory.

**A. S. Dana:** I should like to ask Professor Race whether he thinks it is possible that the hard rubber showed the same phenomenon as the fused quartz (*i. e.*, the reversal during the first short period), but because the period was so short it escaped notice.

**H. H. Race:** In response to the last question, my object in this work was to obtain reliable quantitative data. Because the current changed very rapidly immediately after applying or removing potential, it was impossible to obtain quantitative data during the first minute. It was only in the case of fused quartz that unexpected reversals were observed and the apparatus changed so as to determine qualitatively at least the form of the current curve. In the case of hard rubber no such reversals were evident and no accurate data were sought during the first minute.

# Interconnection of Power and Railroad Traction Systems by Means of Frequency Changers

BY LUDWIG ENCKE[1]

Associate, A. I. E. E.

*Synopsis.—Several types of variable ratio frequency-changers are discussed and installations of such apparatus on the electrified section of the New York, New Haven & Hartford Railroad are described in some detail.*

*These types of frequency-changers permit a flexible tie between interconnected systems, and accurate and automatic control of load regardless of variations in voltage or frequency in either system.*

*Any desired constant load transfer in either direction may be obtained through the apparatus by manually setting a load regulating relay. Provision is made also for operating the sets as synchronous condensers to improve power factor.*

*The functioning of regulating machines and auxiliary equipment to obtain the desired results is explained, together with a description of switching equipment installed in connection with the main units.*

A NUMBER of methods may be employed for connecting two power systems of different frequencies for interchange of power.

At the present time, a rigid tie by means of a synchronous motor-generator is common, and is in many respects the simplest form of connection. Since this rigid connection is wholly dependent upon both frequencies, it does not allow any regulation of the transferred load on the set itself. Furthermore the process of synchronizing is somewhat difficult, since for this purpose the frequency of one system or the other must be changed, and this of course can be done only at the power station. Another type of rigid tie which has been successfully employed consists (in the case for instance of a connection between systems of 60 and 25 cycle) of an induction machine, having a 60-cycle stator and a 25-cycle rotor, mounted on the same shaft with a 25-cycle synchronous machine. The slip-rings of the 25-cycle rotor of the induction machine are connected through a transformer, equipped with taps, to the 25-cycle system to which the synchronous machine is connected. This type of connection not only represents a power and frequency tie but also a voltage tie between the two systems.

A flexible connection is desirable in some instances, and obviously possesses fundamental advantages over any method of rigid tie, in that it permits not only merely tying together two power systems for interchange of power, but a close control of load as well. This may be of especial value in the supply of power for the operation of an electrified steam railroad extending over a large territory, from two or more central station generating plants located along the right-of-way at widely scattered points. In case of a single-phase electrified railroad, it may be necessary to change the 60-cycle power, available in most commercial power systems, into 25-cycle power necessary for traction purposes, at the same time operating in parallel with existing power plants owned by the railroad. By means of flexible connections any desired load distribution among different substations may thus be readily obtained, regardless of variations of frequency in any of the interconnected systems, all variations being absorbed in the machines themselves. Such flexible frequency-changer sets are known as "variable ratio" machines and usually consist of an induction machine, the speed of which is adjustable by means of auxiliary apparatus, mounted on a shaft with a synchronous machine. The speed regulating devices for the induction machine thus employed were originally designed for driving steel mills, etc., when variable speed was required. When used in connection with a frequency-changer set, the auxiliary apparatus usually consists of a three-phase commutator type machine with suitable exciting machines. Another method of obtaining the advantages of a flexible tie between power systems is the application of a rotary converter, (converting the alternating current of one frequency into direct current) in series with a second rotary converter "inverted," which in turn changes the direct current into alternating current of the other frequency. This method, however, is not in common use.

Recently a number of sets of the flexible frequency-changer type (motor-generator) has been purchased for use in connection with the New York, New Haven & Hartford Railroad's electrified system between New York and New Haven.

At present the single-phase 25-cycle system of the New York, New Haven & Hartford Railroad is fed mainly from the railroad's own power plant at Cos Cob, Connecticut. Power is supplied also from the Sherman Creek plant of the United Electric Light & Power Co. at New York. It has been found desirable with increasing loads to provide energy sources on the eastern end of the electric zone and connections have been made at New Haven with the 25-cycle system of the Connecticut Co., a subsidiary of the railroad operating the local street railway system, and at Devon, Connecticut, with the 60-cycle power system of the Connecticut Light & Power Co. In both instances, the connections are by means of "variable ratio frequency-changer sets," which are employed on account of the differences

---

[1] Assistant Engineer, New York, New Haven & Hartford R. R. Co., New Haven, Conn.

*Presented at the Northeastern District No. 1 Meeting of the A. I. E. E., New Haven, Conn., May 9-12, 1928.*

in frequency of the various systems involved, and for the ready control of the power. One unit has been installed in the power plant of the Connecticut Co. at New Haven and two units at Devon in a substation erected immediately outside the plant of the Connecticut Light & Power Co. All the sets are rated nominally at 5000 kw. A fourth set, a duplicate of the New Haven installation, has been installed in the Long Island Railroad's substation at East New York on the Bay Ridge line which has been recently electrified, together with the New York Connecting Railroad as an extension of the New Haven electrification system and receives its power from the New Haven supply. The East New York set is used normally as a rotary synchronous condenser, but is available for transferring power from the three-phase system of the Long Island and Pennsylvania Railroad to the single-phase system of the New Haven or vice versa, as a mutual standby.

Before describing the above mentioned installations in detail, a discussion of the general theory of the speed regulation of an induction motor may be of interest. The speed of an induction motor is fixed by the frequency of the power supply and the number of its poles. When a load is applied the rotor slips slightly, or loses speed. In order to obtain a regulation of the speed, resistance may be inserted in the rotor or secondary circuit of the motor. The current induced in the secondary circuit will thus decrease, and the result is a decrease of the torque and a consequent decrease of speed. Having reached a certain lesser number of revolutions, the current necessary for delivering the torque again flows in the motor's secondary on account of the increased slip voltage. Thus a certain amount of speed regulation of the motor may be obtained by inserting resistance in the rotor circuit. A disadvantage of this method is its lack of economy, since a part of the energy transmitted by the rotating field to the rotor is converted in the resistances into heat and is wasted. Furthermore, the speed regulation is not constant but changes with the torque or load on the motor and of course only regulation below synchronism is possible. Economical methods of regulation have been found in a number of arrangements. The slip energy of the induction motor may be transferred to an additional machine (the so-called regulating machine), where it may be transformed either into mechanical or electrical energy depending on the type of machine employed and thus utilized. By changing the excitation of the regulating machine a variable voltage is produced which, reacting upon the slip voltage, brings about the speed regulation of the induction motor.

The diagrams shown in Fig. 1 illustrate the speed regulation of an induction motor at speeds below synchronism.

Diagram A is the simplified diagram of an induction motor, disregarding reactance and the primary resistance of the machine.

$E_1$ is the primary voltage applied to the induction motor, producing in it the flux $\Phi$; for this purpose the magnetizing current $I_\mu$ is taken from the line or supply. $E_2$ is the voltage induced in the secondary of the motor and $I_2$ is the secondary current. $I_\mu$ and $I_2$ determine the primary current $I_1$ taken from the line.

In diagram B is indicated a counter voltage $E_{REG}$ introduced in the secondary of the induction motor. If the same torque is to be delivered by the motor, *i. e.*, if the same current $I_2$ flows through the rotor, the secondary or slip voltage must be increased to the new value of $E_2'$; thus the speed of the motor drops. $E_2' - E_{REG}$ results in the original secondary voltage $E_2$.

In diagram C it is seen that the regulating machine voltage $E_{REG}$ is not displaced by 180 deg. against $E_2$, but by a certain angle $\Theta$. This voltage $E_{REG}$ may be split up into two components. $E_R$ is the effective counter voltage; $E_x$ is the compensating voltage. The current $I_1$ is almost in phase with the primary voltage; thus power at nearly unity power factor is taken from the supply. The wattless current necessary for the excitation of the induction motor is delivered by the regulating machine due to the compensating voltage $E_x$.

As indicated above, three-phase commutator machines are used as regulating machines for the frequency-changer sets discussed herein. They may be mechanically coupled or driven separately. If the regulating machine is mechanically coupled to the induction motor, *i. e.*, installed on the same shaft or geared to it, it operates as a motor, assisting in driving the main shaft. A portion of the energy from the stator to the rotor of the induction motor is transferred mechanically to the main shaft and a portion is transferred electrically to the regulating machine, being transformed by the regulating machine into mechanical power. Disregarding the losses, the balance diagram is shown in Fig. 2. At any speed, a uniform horsepower is transferred to the shaft; in other words, the arrangement is a constant horsepower drive and the torque increases inversely in proportion to the speed. If, on the other hand, the regulating machine is mechanically separated from the induction motor it may be used to drive a separate machine, such as an induction generator. Only a part of the energy transferred to the rotor of the main induction motor is thus utilized in driving the main shaft, the rest being returned to the line through the regulating machine and induction generator. Dis-

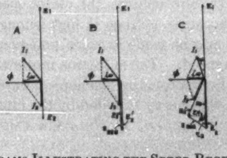

FIG. 1—DIAGRAMS ILLUSTRATING THE SPEED REGULATION OF AN INDUCTION MOTOR

regarding the losses the balance is indicated in diagram Fig. 3. This arrangement therefore represents a constant torque drive, the horsepower of which increases in proportion to the speed.

Thus far regulation only below synchronism, or full-load speed has been discussed. By adding auxiliary apparatus the induction motor may be regulated up to and above synchronism. It is, of course, practically always desirable in the case of variable ratio frequency changers that speed be controlled above as well as below synchronism.

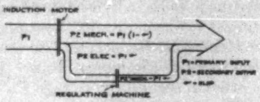

FIG. 2—BALANCE DIAGRAM FOR A CONSTANT HORSEPOWER DRIVE

A normal induction motor can reach practically synchronous speed only under no-load conditions. Its full-load speed lies slightly below synchronous speed. When the voltage of the regulating machine is reversed, thus raising the slip voltage, the motor speed increases, and if this boosting voltage is high enough, the speed of the motor may be made to reach, and even pass above, synchronous speed. The induction motor thus operates as a doubly fed motor, the mechanical output of which is the sum of the energy supplied by the line to its stator and the energy supplied by the regulating machine to its rotor. During operation at exactly synchronous speed the slip voltage, and thus the electrical energy transmitted by the rotation field to the rotor winding of the main motor being zero, the total secondary energy is delivered from the regulating machine, the necessary excitation of that machine being furnished by the above mentioned additional auxiliary apparatus. Above synchronism the direction of the slip voltage is reversed as compared to that of operation below synchronism. The resultant secondary voltage is again as in operation below synchronism the difference between the slip voltage and the voltage of the regulating machine. The secondary current, however, flows in the same direction. The relative directions of the voltage for speeds above and below synchronism are indicated in Table I, the directions for speeds below synchronism having been assumed arbitrarily. The tabulation shows clearly that the secondary current, as indicated, always takes the same direction, at speeds below synchronism as that of the slip voltage, and above synchronism as that of the voltage of the regulating machine.

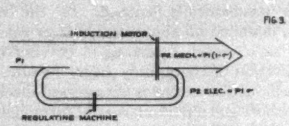

FIG. 3—BALANCE DIAGRAM FOR A CONSTANT TORQUE DRIVE

The speed regulating set in which the regulating machine is mechanically connected to the main shaft also operates at speeds above synchronism as a constant horsepower drive. The additional power taken by the induction motor from the supply line is used to drive the regulating machine, which thus operates as a generator.

TABLE I
DIRECTION OF VOLTAGE AND CURRENT IN THE MAIN INDUCTION MOTOR AND THE REGULATING MACHINE FOR SPEEDS ABOVE AND BELOW SYNCHRONISM

| | Below synchronism | | Between full-load speed and synchronism | | Above synchronism | |
|---|---|---|---|---|---|---|
| Machine | Voltage | Current | Voltage | Current | Voltage | Current |
| Ind. motor stator....... | ↓ | ↓ | ↓ | ↓ | ↓ | ↓ |
| Rotor......... | ↑ | ↑ | ↑ | ↑ | ↓ | ↑ |
| Reg. machine commutator. | ↓ | ↑ | ↑ | ↑ | ↑ | ↑ |

The arrangement in which the regulating machine is mechanically separated from the main shaft is also a constant torque drive above synchronism. As the speed rises, the motor driving the regulating machine (*i. e.*, the induction generator now working as motor) takes increasing power from the line, which is supplied through the regulating machine to the secondary of the main induction motor.

Fig. 4 shows the wiring diagram of the frequency-changer sets installed in the New Haven and East New York substations. They consist of a main set and an auxiliary set. The main set is made up of a three-phase 25-cycle, 11,000-volt synchronous generator with d-c. exciter, a three-phase 25-cycle, 11,000-volt induction motor, the speed of which is determined by the synchronous generator, and the regulating machine which regulates the power flow of the set. The machines of the auxiliary set are, first a synchronous motor used for the drive, second a so-called a-c. exciter machine, and third a d-c. exciter, furnishing the excitation current for the other two machines. The induction motor, the synchronous generator, and the d-c. exciter of the main set are of standard design. The regulating machine is a rotor excited, neutralized a-c. commutator machine, the three-phase wound rotor having slip-rings and a commutator as in a rotary converter. Since the slip-rings carry alternating excitation current only, they are relatively small and the commutator segments are narrow, a feature of every a-c. commutator. The stator has a compensating winding which neutralizes the rotor field generated by the load current in the rotor, so that the machine can transform electrical energy to mechanical energy. The design of this machine is limited by the maximum permissible values of peripheral commutator speeds, the voltage between commutator bars and current densities, a satisfactory design thus requires that the kv-a. output per pole be somewhat limited, and it was desirable in order to obtain the required rating to build the machine at a slower speed than the main unit. The regulating machine, therefore, is connected to the main shaft through a reduction gear with a ratio of two to one and thus rotates at half the speed of the main set.

Fig. 5—Variable Ratio Frequency-Changer Set at Station "A," New Haven

In order to understand the operation of this machine, it may be assumed that the connections from its commutator brushes to the slip-rings of the main induction motor are cut off, and the slip-rings are connected directly to the line.

At stand-still a field will rotate with $n_1 = \dfrac{60\,\nu_1}{p}$ rev. per min. with regard to the stator and rotor, where

$\nu_1$ = frequency of the line

$2\,p$ = number of poles of the machine.

In rotating the rotor with $n$ revolutions opposite to the direction of the field, the resultant speed relative to the space will be:

$$n_1 - n$$

The voltage of the frequency $\nu_2 = \dfrac{p\,(n_1 - n)}{60} = s_2\,\nu_1$

is obtained at the brushes of the commutator, where

$s_2$ = slip.

The effective values of the voltages at the slip-rings and at the commutator brushes are practically equal. When $n_1 = n$, direct current appears at the brushes of the commutator. Therefore, if the regulating machine is given the same ratio of revolutions and number of poles as has the main induction motor, and the slip-rings are fed with line frequency, the slip frequency $\nu_2 = s_2\,\nu_1$ will always appear at the commutator brushes. Thus the commutator brushes of the regulating machine and the slip-rings of the main induction motor may be connected. As the voltages at the slip-rings and at the commutator brushes of the regulating machine are about the same, the latter, and thus the speed of the main set can be easily controlled by changing the voltage applied to the slip-rings of the regulating machine. It is a function of the auxiliary set to furnish to the slip-rings of the regulating machine this variable voltage at line frequency. The continuous delivery of line frequency is insured as the auxiliary set is a straight synchronous motor-generator, connected to the same line as the induction motor. The driving synchronous motor as well as the d-c. exciter are of standard design.

Fig. 6—Regulating Machine and Reduction Gear of the Main Machine Set at Station "A," New Haven

The a-c. exciter machine resembles an induction motor. Its field consists of three windings with a phase angle difference of 120 deg., two of which are connected in multiple. These windings independent of each other, excited by direct current, set up two fields which create a resultant field. The field of the two windings connected in multiple is the load field controlled by the load rheostat, whereas the field of the single winding is the power-factor field, 90 deg. out of phase with the load field, controlled by the power-factor rheostat. The load adjustment of the main set is obtained by changing the voltage generated in the a-c. exciter which is accomplished by varying the load rheostat, while the power factor of the main induction motor is adjusted by changing the power-factor rheostat which is of a potentiometer type. For running above synchronism the voltage of the regulating machine must be reversed; therefore the load rheostat is a reversing rheostat. Both the load and the power-factor rheostats are motor driven.

FIG. 7—AUXILIARY SET AT STATION "A," NEW HAVEN

The following frequencies appear on the various machines and their connections:

| | | |
|---|---|---|
| 1. | From line to stator of induction motor... | line frequency $\nu_1$ |
| 2. | In rotor of induction motor............. | slip frequency $\nu_2$ |
| 3. | From slip-rings of induction motor to commutator of regulating machine.. | slip frequency $\nu_2$ |
| 4. | From slip-rings of regulating machine to slip-rings of a-c. synchronous exciter.......................... | line frequency $\nu_1$ |
| 5. | From stator synchronous motor to line............................ | line frequency $\nu_1$ |

The regulating set works as a constant horsepower drive, as all the energy taken from the line is transferred into mechanical power on the main shaft, neglecting the losses in the machines.

As outlined above this variable ratio frequency-changer set represents an interconnection between two 25-cycle systems. If, however, the induction motor is a 60-cycle machine the excitation for regulation would also be 60-cycle. The inherent frequency is then higher, a condition which is not desirable with rotor excitation on so large a set. Some other arrangement is thus necessary. This condition may be taken care of by replacing the rotor excited regulating machine by a stator excited type.

A slightly different means of regulation known as the Scherbius system is employed in the installation at Devon. The same system may be applied to connections between two 25-cycle systems or between a 60-cycle and a 25-cycle system.

Figs. 8, 9, 10 show single-line wiring diagrams for various applications, as follows:

These three wiring diagrams are perhaps especially interesting in their assemblage, in showing the progressive simplification.

Fig. 11 shows the three-line wiring diagram of the Devon set.

The frequency changer arrangement shown in Fig. 8 consists of a main and an auxiliary set. The latter includes the regulating machine and the induction machine, which at under synchronous speed operates as a generator driven by the regulating machine, and returns the slip energy back to the line. During operation above synchronism, however, the induction machine works as a motor and drives the regulating machine, which as a generator feeds the secondary of the main induction motor. The induction machine is of standard design. This set operates at a constant torque, while the arrangements shown in Figs. 9, 10, 11 show a constant horsepower drive, as the regulating machine is mounted on the main shaft.

The synchronous generator, its d-c. exciter, and the main induction motor have no unusual features. Common to these regulating sets and resembling in appearance a d-c. machine is the Scherbius regulating machine. Like a d-c. machine, it has main poles and interpoles. The excitation, however, is alternating current instead of direct current. As the frequency of the excitation voltage determines the frequency at the commutator brushes which are connected to the slip-rings of the main induction motor, the regulating machine must be excited with slip frequency. Furthermore, the voltage existing at the commutator brushes, and thus the speed of the regulating set, is controlled by varying the excitation voltage.

This excitation voltage is furnished from the line through a special auxiliary machine known as an ohmic drop exciter or frequency changing exciter which works as a frequency converter. Its operation resembles that of the regulating machine previously described. The rotor is analogous to the rotor of a rotary converter in that it is three-phase wound, and has slip-rings as well as a commutator. The stator has no field winding, and is merely a laminated steel ring to provide a flux path. The slip-rings are connected through a transformer to the line. Since it is mechanically coupled to the main induction motor and has the same number of poles, a voltage of slip frequency exists at its commutator brushes, which is employed for the excitation of the regulating machine. The commutator carries two sets of brushes which are moved by a brush-shifting device, and the regulation of the excitation voltage is accomplished by shifting these brushes. That is, by moving the brush-shifting device in one direction or the other, more or fewer commutator bars are included between the brushes, and the excitation voltage applied to the regulating machine is thus raised or lowered. The brush-shifting device provides for operation at under synchronous as well as above synchronous speed by reversing the excitation voltage. Two contactors *A* and *B* are provided in the connections between the ohmic drop exciter and the regulating machine. During under synchronous operation as well as at synchronous speed contactor *B* is closed, connecting the ohmic drop exciter to the Scherbius machine through its interpoles, whereas above synchronous speed the contactor *A* is closed, connecting the ohmic drop exciter directly to the Scherbius machine.

As in the regulating sets of other types, these sets also are equipped with apparatus to correct the power factor of the main induction motor. As shown in the wiring diagram Fig. 11, the so-called power-factor rheostat is connected in series with the load control field windings of the regulating machine. The degree of lag of the exciting current behind the voltage can be varied in changing the resistance of these windings by means of the rheostat. The regulating machine is equipped in addition with separate power-factor control windings, which are used when no excitation is supplied to the load control field circuit, the first method described for power factor correction being under these conditions ineffective. These separate power-factor control windings are connected from one set of brushes through a second section of the power-factor rheostat to a star point. The voltage supplied to the power-factor control windings is constant and about in quadrature to that of the load control field. As the excitation in the load control windings is increased, the effect of the power-factor control windings is reduced. Before the application of the automatically controlled power-factor rheostat, which is described below, was contemplated, an additional apparatus for power factor correction known as a "bulging transformer" together with a manually operated power-factor rheostat was considered. As shown in the wiring diagrams Figs. 8 and 9, the ohmic drop exciter is fed by its line transformer through the secondary of the bulging transformer, while the stator current of the main induction motor (fed from the line) flows through the bulging transformer primary. The voltage induced in the secondary of the bulging transformer (varying with the load on the induction motor) and the voltage furnished by the ohmic drop exciter transformer, are out of phase, and when combined obviously create a resultant voltage. This resultant voltage applied to the slip-rings of the ohmic drop exciter, changes automatically with the load. Additional control is accomplished in this case, as indicated above, by means of a manually instead of an automatically operated power-factor rheostat. Both brush-shifting device and power-factor rheostat are motor operated.

All of the regulating sets discussed above are started from the induction motor side of the main set by inserting resistances in its secondary. When an auxiliary set is used, it is connected to the line at the same time or shortly before the main set. After the induction motor has reached its full speed, its secondary slip-rings are connected to the commutator of the regulating machine; thus, the load which is to be transferred and the power factor of the main motor may be adjusted. Full automatic starting of the sets has been provided in all cases.

The synchronous generators furnishing the single-phase railroad power are built as three-phase machines, having the single-phase rating as shown in Table IIA. The stators are all spring mounted, in order to reduce vibration due to the single-phase load. These springs are installed on both sides of the stators which are thus entirely supported by them. Leaf springs are used at New Haven and East New York, while at Devon, helical springs are employed.

All installations are equipped with automatic load regulators which, when adjusted for any given kw. value, provide that during all variations of frequency in the interconnected systems, within the allowed limits as described below, the transferred kw. load shall remain constant. Two different types of load regulators are used; in the New Haven and East New York substations a rheostatic type is installed, while those in the Devon substation are of a polyphase induction type.

The rheostatic type load regulator has as a control element two solenoids, one of which carries a current and a voltage coil, energized from a current and a potential transformer in the single-phase generator circuit, and connected in such a way, that its pull is proportional to the single-phase kw. load. The plunger of this solenoid acts on a lever arrangement, which carries a double acting circuit closing contact. The second solenoid which is energized through two d-c. coils acts on the same lever arrangement to prevent hunting. A variable anti-hunting rheostat is also connected into the circuit of one d-c. winding. Two dash pots stabilize the operation of the control element, and the pull of the alternating current aided by counterweights balances the weight of the core. A variable rheostat, a so-called load adjusting rheostat, is connected in parallel to the current coil of the a-c. solenoid. By means of this rheostat, more or less current can be shunted through the a-c. coil, and various values of kw. load can be obtained by means of a calibration dial which is graduated in terms of kilowatts. The load regulator is in equilibrium for a given kw. value dependent on the position of the load adjusting rheostat. As soon as the output of the single-phase machine varies, this equilibrium is destroyed and the double acting contact mentioned above will close in one or the other direction. Two reversing contactor switches are provided and are energized over the main contact of the control element. If the load drops below the value for which the regulator is set, the main contact closes, energizing one of the reversing contactor switches, which in turn allows the current to flow through the armature of the motor driving the load rheostat and turning it in the "raise" direction. If the load increases above the value as fixed by the setting, the other reversing contactor switch is energized resulting in the rotation of the rheostat driving motor into the "lower" direction. The motor is a shunt motor, the field of which is permanently energized. The reversing contactor switches have two additional contacts, which are closed when the switches are deenergized. The motor and the switches are connected in such a way that the armature of the motor is short circuited when the additional contacts of both switches are closed. The dynamic braking, thus applied to the motor, stops it almost instantaneously when the control element's contacts are open, *i. e.*, when the regulator is in equilibrium.

Fig. 12—Variable Ratio Frequency-Changer Sets in the Substation at Devon

The polyphase induction type load relay as installed at Devon is similar in its construction to a polyphase watthour meter. The relay has two stationary electromagnetic elements consisting of a current winding and a potential winding with laminated steel magnetic circuits. These windings are energized from a current and a potential transformer in the three-phase induction motor circuit and the two elements react on two disks on a single vertical shaft. They are suspended from a torsion wire and operate a double throw circuit closing contact. Two permanent magnets are used to damp the rotation of the disks. The torsion wire balances against the pull of the elements and its tension can be manually changed. For this purpose a knob and a scale graduated in kilowatts are provided, allowing the setting of the relay for each desired kw. value within the capacity of the machine set. As soon as the load varies from the value for which the relay has been set the double throw main contact closes. This energizes by means of an instantaneous auxiliary relay the "raise" or "lower" relay, which in turn closes the armature circuit of the motor driving the brush-shifting device on the ohmic drop exciter in one direction or the other. These latter relays have also additional contacts, which are closed in order to permit dynamic braking, when the relays are deenergized. The armature of the motor, (which in this case is a series motor), is short-circuited when these contacts of both relays are closed, while the series field winding of the motor remains energized over an inserted resistance.

Fig. 13—Secondary Starting Panel and Resistances, and Power-Factor Rheostat in the Substation at Devon

In all the substations, the load regulation of course can be performed manually as well as automatically. In the case of the New Haven and East New York substations a two-position control switch is provided to accomplish these two modes of operations, while at Devon, a control switch for the manual operation and a transfer switch for changing to automatic control are installed. The technique of placing the machines under the control of the automatic regulators is very simple in all the installations. After the generator is synchronized with the railroad power system, the control switch or the transfer switch is placed in its "regulating" position and the load adjusting rheostat at New Haven and East New York and the knob of the load relay at the Devon substation are adjusted slowly until the pointers indicate on the scale the load which it is desired to carry.

All frequency-changer sets under discussion can of course fundamentally transfer power in either direction; nevertheless only the sets at New Haven and East New York are specifically intended for interchange of power, the installation at Devon being arranged to transfer power only from the 60-cycle system to the 25-cycle system.

The range of the frequency regulation of the sets is shown in Table IIA.

The regulating sets installed at the New Haven and East New York substations (Fig. 4) and at Devon (Fig. 11) as mentioned above are constant horsepower drives. In the design of speed control for steel mill motors the decision as between a constant horsepower or a constant torque drive is determined by local operating conditions. This does not apply to frequency changers, and either form of drive may be applied. Nevertheless the demands of a frequency changer are of course more those of merely a constant horsepower drive. When the machines are once adjusted for a given load the transferred horsepower must remain constant independent of frequency (*i. e.*, speed variation) in either or both of the two systems connected. It is to be noted that a constant horsepower drive, as has been pointed out, involves one auxiliary machine less than a constant torque drive.

Table II contains technical data of interest in connection with the various sets discussed.

Having considered the different types of variable ratio frequency changer sets, it may be of interest to note briefly the general layout, the switching equipment, the protective devices, and the operating conditions of the machine sets installed in the two substations at New Haven and at Devon.

The variable-ratio frequency-changer set at New Haven has been installed as an interconnection between the systems of the N. Y., N. H. & H. R. R. Co. and of the Connecticut Co., in the power plant of the latter company at New Haven, Connecticut, which is known as Station A. The existing power plant building has been extended one bay and the main set is installed on the operating floor, with the auxiliary set on the main floor below. A mezzanine platform was erected on the steel foundation of the main unit, between the main and the auxiliary sets, for the secondary resistances of the main induction motor, the load and power-factor rheostats and the tie breaker. The switching equipment and the switchboard are built as extensions to the existing equipment of the Connecticut Co. and conform as far as possible to existing conditions. All operations for starting and operation of the set are controlled from the switchboard. The main induction motor is designed for forced ventilation by means of a motor-driven fan. The bearings of the main set are water-cooled and self lubricating.

Fig. 14 shows a wiring diagram of the machine set and indicates the instruments and protective devices used. The automatic protection of the set includes the protection of the various machine units and the means to secure the proper starting sequence. The main induction motor as well as the generator is equipped with differential relays to protect against internal faults. For the protection of the synchronous generator against excessive overload, especially when operating as a condenser, the voltage regulator is provided with a device for limiting the field current. The auxiliary set together with the blower motor is fed through fuses from the 440-volt auxiliary busses of the power plant.

A number of interlocking devices provides a proper starting sequence. The starting of the set is possible only when the load field rheostat and the power-factor rheostat are in their neutral positions, to which they are brought manually. Furthermore the tie breaker connecting the slip-rings of the main induction motor to the commutator brushes of the regulating machine must be opened. For this purpose, this breaker is interlocked with that of the main induction motor in such a way that tripping the latter trips the tie breaker automatically. An interlock between the breaker of the auxiliary set and the main induction motor breaker insures that when one trips the other one is tripped automatically. The load and the power-factor rheostats being in proper positions, the closing of the control switch of the main induction motor breaker opens the starting sequence. The secondary resistances of the main motor are short-circuited step by step, as controlled by accelerating relays, which allow the short-circuiting of the next resistance step only after the primary current is lowered sufficiently. At the same time, the auxiliary set and the blower motor start. Full voltage is applied to the stator of the synchronous driving motor of the auxiliary set (which is provided with a damper winding), and its field is short-circuited over the field discharge resistance. After reaching full speed and after building up the voltage of the d-c. exciter of the auxiliary set, the discharge circuit is opened and the field is connected to the d-c. exciter machine, and the tie breaker closes. The speed regulation can now be applied by manipulating the load-field rheostat, facilitating the synchronizing of the generator with the railroad supply. The blower motor is a squirrel-cage motor, which is started with full voltage and speeds up to its constant speed. The set is now ready to supply power from one system to the other.

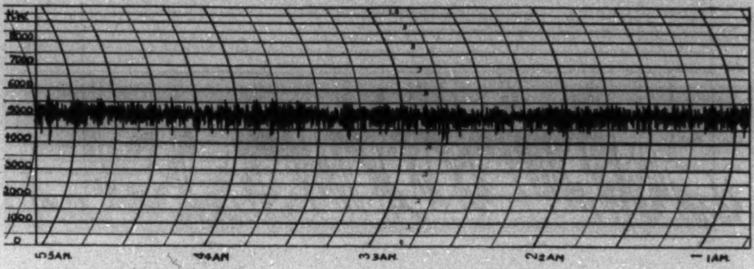

Fig. 15—Kw. Load on the Frequency-Changer Set at New Haven

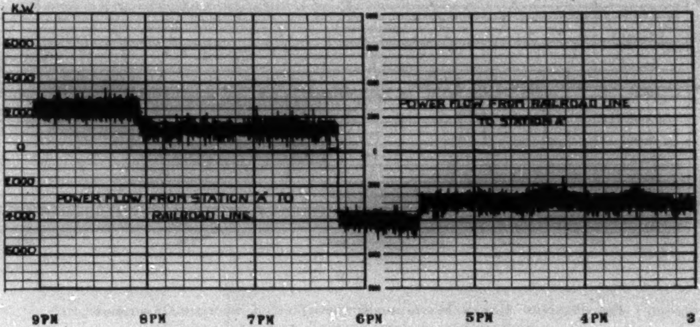

Fig. 16—Kw. Load Curve for Power Flow in Both Directions

Typical for every single-phase railroad load are the heavy and sudden swings of the load in kilowatts as well as the reactive kv-a. load. Nevertheless, in putting the machine under the control of the automatic load regulator, a given kw. load representing a base can be accurately maintained, while the swings are taken up by another source of supply. Any desired load within the capacity of the machine can thus be adjusted. Fig. 15 shows such a kw. curve; in this instance the automatic load regulator was adjusted for a value of 5000 kw., and it is of interest to note how the load was kept constant within comparatively narrow limits, in spite of the widely varying system load.

As previously mentioned the sets at New Haven and East New York have been arranged for power flow in both directions. Fig. 16 shows such an operation.

The sets at New Haven and at Devon as well as that at East New York are operated part of the time as motor-generators and part as synchronous condensers. It is obvious that when running as a synchronous condenser, a constant wattless output cannot be sustained if the voltage is to remain constant. The wattless output of lagging current or in other words the wattless input of leading current is carried by the machine as may be necessary; that is, the machine performs the function of keeping up the line voltage by putting out wattless current to take care of the wattless load. During such a period, the power plant at Cos Cob, of course, shows a power-factor improvement. But as soon as the which, as soon as the machine is overloaded, reduces the voltage and in doing so the wattless current carried. Safe operation as a rotary condenser without this current-limiting device would be difficult. Figs. 17A and B show the operation of the machine at New Haven as a synchronous condenser under normal conditions. A represents the amperes carried and B the voltage. Figs. 18A and B represent also synchronous condenser operation but under unusually severe load conditions. The ampere curve is of interest on account of showing the highly swinging wattless load; the influence of the "moving" wattless load is in the vicinity of Cos Cob, the wattless current is furnished from there, and the synchronous condenser at New Haven thus runs more or less idle. Obviously, it would be impossible to keep constant the reactive kv-a. load of the synchronous condenser, since the voltage regulator is set for maintaining voltage at a desired value and tends to keep this voltage constant by varying the excitation of the machine; that is, for carrying varying reactive kv-a. load. It is for this reason, as above stated, that the regulator is equipped with a current-limiting device, current-limiting device can be recognized very clearly in the voltage curve.

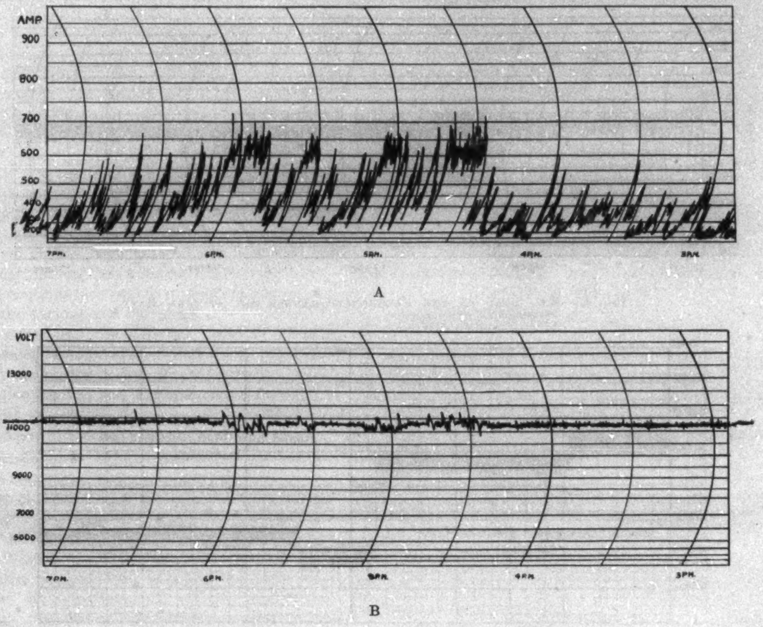

FIG. 17—NEW HAVEN MACHINE, RUNNING AS SYNCHRONOUS CONDENSER

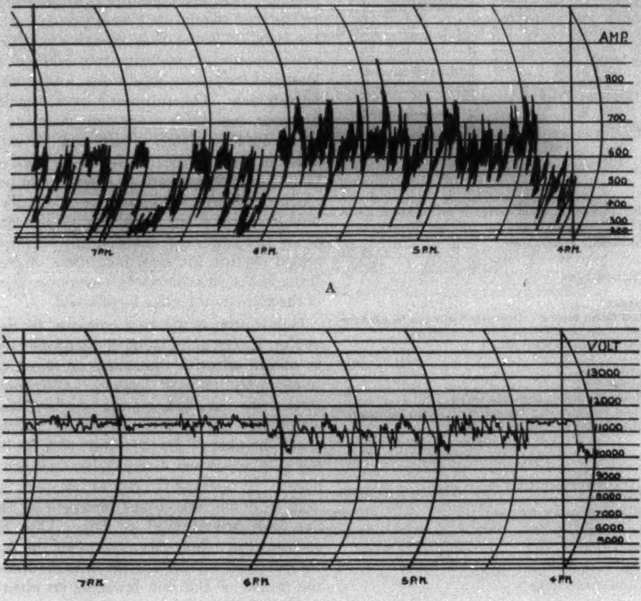
*a* = current *b* = voltage at terminals

At Devon, Connecticut, where is located the interconnection between the systems of the N. Y. N. H. & H. R. R. Co. and of the Connecticut Light & Power Co., a substation building was erected outside the power plant for housing the frequency-changer sets and their associated equipment. The two machine sets are installed on the main floor, and the auxiliary equipment, such as secondary starting panels and resistances for the main induction motors, the various rheostats, and the transformers for the ohmic drop exciters, in the basement. A special room is provided for the switchboard. Outside of the building on one side are the 60-cycle busses, transformers, oil circuit breakers, and the incoming feeders, while on the opposite side are located the 25-cycle busses, transformers, and outgoing feeders to the railroad system. The substation is operated by the Connecticut Light & Power Company.

All machines are self ventilated. The single-phase generators, as above stated, may be operated as synchronous condensers. The bearings are water-cooled and self lubricating during running; during starting, however, an oil pump supplies oil under pressure to lift the rotating element from the bearings in order to reduce the break-away torque.



A

B

Fig. 18—Synchronous Machine at New Haven, When Running as a Synchronous Condenser Under Unusually Heavy System Load Conditions

*a* = current *b* = voltage at terminals

Fig. 19 shows the wiring diagram indicating the instruments and protective devices used. Here, too, the main machines are protected by differential relays against internal faults. In addition the induction motor circuits are equipped with overload relays. The ohmic drop exciters also have overload protection, which operates to open the main breakers, thus shutting down the whole set. The synchronous generators are protected against excessive overload by a current limiting relay connected to the voltage regulators. Before starting, the power-factor rheostat is in its "all in" position and the brushes of the ohmic drop exciter in their neutral position, having been brought to these positions automatically when the set was shut down.

These sets are started automatically by simply closing the main induction motor circuit breaker. The secondary resistances of the induction motor are short circuited step by step, as controlled by timing relays, which allow the short-circuiting of the next resistance step only after a certain given time, the steps in this instance not being a function of current. The final connection between the slip-rings of the main induction motor and the commutator brushes of the regulating machine is performed by contactors as the last step of the starting sequence.

Normally one set only is operated either as a tie or as a synchronous condenser, the other one being held as a spare unit except in emergency. Fig. 20 shows a kw. curve, when the machine is under the control of the automatic load regulator. This curve is of interest in comparison with Fig. 21, which shows the typical variation of the kw. output of the power station at Cos Cob to the eastern part of the line. Figs. 22A and B show the ampere and the voltage curves, when operating as a synchronous condenser. As stated previously, the automatic load regulator in the case of the New Haven set is controlled by the single-phase output of the synchronous generator, whereas the automatic load regulator of the Devon set is inserted in the three-phase circuit of the main induction motor.

All frequency-changer sets are equipped with automatic reactive kv-a. regulators for the main induction motor. They are similar in construction and operation to the load regulators already described. The regulator installed in the New Haven substation maintains a power factor of approximately 100 per cent under all load and frequency conditions, and does not allow any adjustment. The automatic kv-a. regulator at Devon, however, maintains a constant reactive kv-a. value of the induction motor, which can be adjusted to any value in such a way that for every load setting a power factor up to 90 per cent or even to 100 per cent may be reached. These automatic kv-a. regulators are desirable to increase the simplicity of operation, inasmuch as in the course of maintaining a constant predetermined load on the sets, regardless of frequency variations in the interconnected systems, the power factor of the main motors may be affected.

One feature of interest common to the installations at New Haven and Devon is the protective arrangement to obtain selective operation on short circuits on the single-phase railroad system. Current-limiting resistances are installed on the single-phase ends of the machines, which are normally short-circuited by circuit breakers. In the event of a fault or ground on the railroad system, these resistances are automatically inserted by opening the circuit breakers, after which the local sectionalizing circuit breakers on the line feeding the fault are allowed to trip. The resistances are automatically short-circuited after the faulty section is cut out, and normal operation is resumed. In case of the failure of the line breakers to clear the line, the whole substation is separated from the railroad line after a predetermined time by the opening of the main circuit breakers.

The installations at Devon and New Haven were

Gibbs & Hill, New York, acted as consulting engineers for all the installations.

## Discussion

For discussion of this paper see page 1079.

# Application of Large Frequency Converters to Power Systems

BY E. J. BURNHAM[1]

### APPLICATION OF LARGE FREQUENCY CONVERTERS TO POWER SYSTEMS

IN selecting a frequency converter, there are many things which should receive special study and consideration in order that the equipment obtained will meet the necessary requirements in the best possible way.

The purpose of this paper is to discuss frequency converter sets and their use as a means of connecting systems of different frequency.

Systems of different frequency are connected together for the same reasons that systems of the same frequency are connected; namely, to save capital investment in generating equipment, and improve service to customers. By interconnection, the generating capacity of one system is made available for another, which may mean a large total saving and furthermore provides another source of power supply which may be of great value in emergencies when stations or transmission lines are out of service.

A somewhat different application is the use of frequency converter sets to connect power systems with railway and industrial systems, where the frequency of the power required by the railway or industrial load is different from the power system frequency.

The different points to be considered in choosing a frequency converter are considerably interwoven, so at best a compromise selection may be necessary. The type of set to be used should, without doubt, be determined largely by the particular characteristics and the operating requirements of the two systems to be interconnected. However, there are other points which may require special consideration, such as design, efficiency, operation, maintenance, and cost.

### TYPES OF FREQUENCY CONVERTERS

The following types of frequency converters will be considered:

1. Synchronous-synchronous type, consisting of a synchronous motor direct-connected to a synchronous generator.
2. Induction-synchronous type, consisting of an ordinary induction motor direct-connected to a synchronous generator.
3. Adjustable-ratio induction-synchronous type, consisting of a wound rotor induction motor direct-connected to a synchronous generator, the induction motor having suitable control equipment to give a variable frequency ratio between the two systems to be connected together.
4. Fixed-ratio induction-synchronous type, consisting of an induction frequency converter direct-connected to a synchronous generator. The rotor of the induction motor is connected electrically to the stator of the synchronous unit, thereby allowing electrical, as well as mechanical transfer of power through the set.

### SYNCHRONOUS-SYNCHRONOUS TYPE

With the synchronous-synchronous type of frequency converter, both units necessarily operate in synchronism, forming a rigid frequency tie between the two systems connected together. Therefore, with this type of set, the ratio between the frequencies of the two systems must normally remain constant.

In the past, the majority of frequency converter sets used have been of the synchronous-synchronous type because such sets are adaptable to simplicity of design and operation and may have low costs, high efficiency, and ability to correct power factor. Sets of this type can be sturdy and simple in design and have a minimum number of auxiliary parts. This results in minimum attention and low maintenance costs, which are important points.

The power factor of either machine may be conveniently adjusted by field control. Furthermore, if the set is not being used as a tie, either machine may be used as a synchronous condenser.

The load transferred through this type of set must be controlled by governor adjustments on the prime movers of either or both interconnected systems. Usually, this introduces no great hardship in operation, but in some cases it is a very inconvenient way of holding load on the frequency converters, particularly if the principal generating units of the interconnected systems are controlled by other companies.

In case it is desirable to synchronize the two systems at a frequency converter station, the governors of the prime movers must be adjusted until synchronizing can be accomplished. This again may be inconvenient, as it usually means telephoning to some distant generating station.

In using a frequency converter set of the synchronous-synchronous type, the capacity of the set may be determined by the size of the set that will reasonably hold the two systems together, rather than by the size of set required to transfer the amount of power desired. This would be a hardship in case it should be desired to transfer a small amount of power between two large systems of different frequencies.

Although normally the ratio of the frequencies at each end of a synchronous-synchronous set must remain constant, nevertheless there may be fluctuations in frequency or frequency ratio. Fluctuation in frequency on either or both systems causes load variation on the set and if the fluctuations in frequencies are severe enough, the set will pull out of step. Synchronous machines of this class are normally designed for 50 per cent momentary overload before the pull-out point is reached. In special cases, frequency converter sets may be designed for greater momentary overloads reaching values as high as 200 per cent. This means that momentary fluctuations in frequency or frequency ratio may occur and a set still maintain synchronous operation, provided load changes do not load the set above the pull-out point.

*Presented at the Northeastern District, No. 1, Meeting of the A. I. E. E., New Haven, Conn., May 9-12, 1928.*

Excitation for the fields of the synchronous machines may be provided by two direct-connected exciters, one mounted on each end of the set, each arranged to excite the field of one synchronous unit. This gives a very flexible and dependable method of excitation. Sometimes the excitation for both main units is obtained from one direct-connected, or one motor-driven exciter. With this arrangement, individual field control is obtained by the use of rheostats in the field circuit of the main units. The use of such rheostats introduces rheostat losses, and furthermore, the use of a common excitation scheme has the disadvantage that any excitation trouble involves the excitation of both units.

FIG. 1—20,000-KW., 300 REV. PER MIN. SYNCHRONOUS-SYNCHRONOUS FREQUENCY CONVERTER

Motor-operated, phase-shifting devices may be furnished on frequency converter sets when the sets are to operate in parallel. Such a device mounted on one of the machines of each set permits control of load division between sets and enables the operator to add, or remove, a set from the line without any sudden jolt to the system. The phase shifting is accomplished by mounting the stator of one of the machines of the set in a cradle in such a manner that the stator may be physically rotated with respect to the stator of the other unit.

Fig. 1 shows a 20,000-kw. 300-rev. per min. synchronous-synchronous frequency converter recently placed in operation at Providence, Rhode Island, to connect the New England Power Co. 60-cycle system with the United Electric Railway 25-cycle system. The 60-cycle machine is rated three-phase 11,000 volts unity power factor and the 25-cycle machine is rated single-phase 11,000 volts unity power factor. The tested over-all efficiency of the set is 96.26 per cent.

### INDUCTION-SYNCHRONOUS TYPE

Sets of the induction-synchronous type consist of an induction motor driving a synchronous generator and are very similar in normal operation to the synchronous-synchronous type of set, except that the frequency ratio varies slightly with load on the set, due to the slip of the induction motor. The induction motor may be either of the squirrel-cage or the wound-rotor type. The load on one of these sets is controlled in the same manner as the load on a synchronous-synchronous type of set, namely, by adjustment on the governors of the prime movers of either or both systems interconnected. When load on the set is changed, the ratio of frequencies on the two systems is necessarily changed at the same time, which is an undesirable factor in some cases. The straight induction motor, of course, lacks in itself the ability to correct power factor, and therefore cannot furnish leading current, or be utilized as a synchronous condenser when the set is not in use as a tie.

Division of load between two sets operating in multiple cannot be accomplished by a stator phase shifting device, because two induction synchronous sets operating in multiple will divide load according to their speed regulation, and not in accordance with difference in phase position. A change in phase position will not change the speed; therefore the load will remain the same.

### ADJUSTABLE-RATIO INDUCTION-SYNCHRONOUS TYPE

By means of frequency-converter sets of this type, flexible frequency ties are formed between the systems connected together. The two main units consist of a synchronous machine direct-connected to a wound-rotor type induction machine. These two units are not required to operate in synchronism, as was the case with the synchronous-synchronous type. By means of auxiliary equipment, the direction and amount of power transferred through the set is controlled while the frequencies, or frequency ratio, of the two systems may vary within the limits for which the apparatus is designed.

The outstanding features of this type of set are as follows:

1. The ratio of the two system frequencies may vary.
2. Direction and amount of load transferred through the set may be controlled at the set itself.
3. The speed of the set may be controlled for synchronizing purposes.
4. The capacity of the set is determined only by the amount of power to be transferred through the set, as it is not necessary to furnish synchronizing power to hold the two systems together.

5. Leading current for power-factor correction may be furnished by the set to either system.

6. System disturbances will not pull the set out of step as easily as a set of the synchronous-synchronous type.

The synchronous unit of the set is of standard construction, such as used in the ordinary synchronous-synchronous frequency-converter set. The induction unit is of standard three-phase construction with phase-wound rotor, the selection of the secondary voltage being suitable for operation with auxiliary equipment to be described later.

Power may be transferred through the set in either direction by speed control of the induction unit which tends to make the machine operate above or below synchronism. Due to the fact that the speed of the set actually follows the speed of the synchronous unit, any tendency to increase the speed of the induction unit causes flow of power from the induction to the synchronous end and any tendency to decrease the speed of the induction unit causes flow of power from the synchronous to the induction end. The control of power flow in this manner is very similar to the control of a prime mover direct connected to a generator, where output is governed by speed control.

Several methods[2] have been developed for operating induction machines above and below synchronism, one of the principal applications being in steel mill work. The schemes so developed are available for controlling induction machines of adjustable-ratio frequency converters.

All of the schemes referred to are based upon the fundamental principle that the speed of an induction motor may be controlled by controlling its secondary voltage. In the ordinary induction motor, the speed is controlled by adjusting the secondary resistance, increased resistance having the effect of increasing the voltage drop in the resistors and opposing the flow of secondary current. The slip of the induction machine must always be such as to generate voltage sufficient to force through the impedance of the secondary circuit, the amount of current necessary to develop the required torque. If external resistors are used in the rotor circuit to control the speed, the secondary voltage across the resistors is always at slip frequency.

The resistance method of controlling speed of induction motors is not entirely suitable for use in controlling the induction machine of an adjustable-ratio frequency converter, because by this method, only speed control below synchronism is obtained for motor operation and only above synchronism for generator operation. Furthermore, this method permits undesirable rheostat losses. In order to have speed control of the induction machine above, below, and at synchronous speeds for a definite direction of power flow, some scheme such as used for control of steel mill motors is necessary.

In these schemes, the resistor is replaced by a regulating machine, which inserts a voltage of slip frequency in the rotor circuit of the induction unit. When this regulating machine operates as a motor, power is taken from the induction motor rotor, just as would be the case if a resistor were used, but with less loss. When the regulating machine operates as a generator, it corresponds to a negative resistance placed in the induction motor rotor circuit, furnishing power to the induction motor rotor, and giving speed control above synchronism.

In order to present a better idea of just how one of these regulating machines may be applied to an adjustable ratio frequency converter, some of the details of the Scherbius type sets will be mentioned.

FIG. 2—6000-KW. ADJUSTABLE-RATIO INDUCTION-SYNCHRONOUS FREQUENCY CONVERTER

Regulating set is shown in foreground—Installation is in Rochester substation

Seven adjustable ratio frequency converters of the Scherbius-controlled type are now in operation. Five of these sets are rated 6000 kw., and two are rated 5000 kw.

Two of the 6000-kw. sets were installed in 1924, at Rochester, N. Y., where they connect the Niagara, Lockport & Ontario Power 25-cycle system with the Rochester Gas & Electric Company 60-cycle system, (see Fig. 2). Two additional 6000-kw. sets were installed in 1925 at Altmar, N. Y., where they connect the 25-cycle system of the Niagara, Lockport & Ontario Power Company with the 60-cycle systems of the Northern New York Utilities and Mohawk-Hudson. The other 6000-kw. set was installed at Falconer, N. Y., to form a connection between the Niagara, Lockport, & Ontario Power Company 25-cycle system and the 60-cycle systems of Western Pennsylvania. The two 5000-kw. Scherbius-controlled sets were recently installed at Devon, Conn., where they form a connection between the Connecticut Light & Power Company's 60-cycle system, and the New York, New Haven & Hartford Railway Company's 25-cycle system.

[2] *Theory of Speed and Power Factor Control of Large Induction Motors by Neutralized Polyphase A-C. Commutator Machines*, by J. I. Hull, A. I. E. E. TRANS., 1920, Vol. 39, p. 1135.

"Three-phase Speed Regulating Sets with Separate Excitation," *E. T. Z.*, 47, p. 989, Aug. 26, 1926.

A wiring diagram of the Rochester 6000-kw. Scherbius-controlled, adjustable-ratio frequency converter set, is shown in Fig. 3. The equipment includes a main set, a regulating set, and auxiliary equipment. The main set consists of a 10-pole 7500-kv-a. three-phase 60-cycle 720-rev. per min. 11,000-volt, 80 per cent power factor synchronous unit, a 4-pole 8500-hp., three-phase 25-cycle 11,000-volt, unity power factor induction machine, a 50-kw. 125-volt d-c. exciter, and a 7.5 kv-a. 25-volt a-c. exciter. The regulating set consists of a 475-hp. three-phase 25-cycle squirrel-cage induction motor, direct connected to a 300-kv-a. regulating machine which is a three-phase commutator type unit.

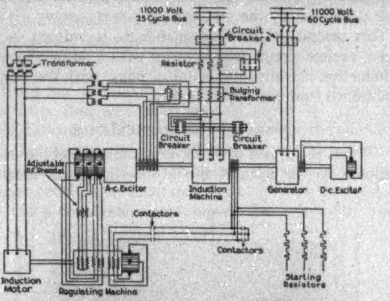

Fig. 3—Diagram of Connections for a 6000-Kw. Adjustable-Ratio Induction-Synchronous Frequency Converter

## Regulating Machine

The requirement of the regulating machine is to supply a voltage to the collector rings of the main induction unit, this voltage being at slip frequency and having a magnitude and phase angle controllable by the operator.

The construction of the regulating machine rotor is similar to that of a d-c. motor. Three sets of brushes on the commutator furnish the required three-phase voltage which is applied to the main induction motor rotor. As the regulating machine is completely neutralized, the current taken from the brushes on the commutator passes through a neutralizing winding on the stator which has the same effective number of turns as the rotor winding. In this way, the armature reaction is neutralized, the turns of the rotor and stator being opposed and balanced.

Due to the fact that it is sometimes considered difficult to obtain good commutation on a-c. commutator type machines, it is of interest to note that commutation on the regulating machine described is exceptionally good.

The regulating machine has the characteristic that whatever frequency is used in its excitation, voltage of that same frequency will appear at the armature terminals. Therefore for this application, it is necessary to furnish the regulating machine with excitation at slip frequency. Furthermore, means must be furnished for controlling the magnitude and phase angle of the excitation in order that the magnitude and phase angle of the armature voltage may be controlled. This required excitation is obtained from the a-c. exciter mounted on the shaft of the main set, as shown in Fig. 3.

## A-c. Exciter

Fig. 4 shows a close-up view of the a-c. exciter. The rotor of this unit has both collector rings and a commutator, and is similar in construction to the rotor of a rotary converter. Power is taken from the commutator through three sets of brushes spaced 120 electrical degrees apart. Means is provided for shifting the brushes, as will be described later. The stator punchings have neither slots nor windings, but provide a path for the revolving flux set up by the three-phase rotor current. The a-c. exciter is really a frequency-changing exciter, as it receives power at line frequency and converts it to slip frequency.

The energy taken from the commutator of the a-c. exciter is always at slip frequency for the following reasons: The a-c. exciter has the same number of poles as the main induction unit and is connected on the shaft of the main frequency converter. The collector rings on the a-c. exciter are connected to the same source of power as the stator of the main induction machine. The voltage supplied to the slip rings creates a magnetic field, which revolves at synchronous speed with respect to the a-c. exciter rotor. The direction of rotation of this magnetic field is opposite to the mechanical rotation of the exciter. The frequency of the voltage taken from the commutator is, therefore, determined by the speed of rotation of the magnetic field in space, and thus is always at slip frequency.

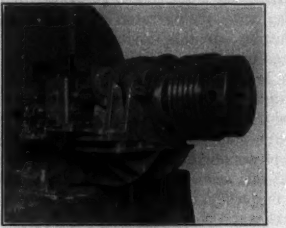

Fig. 4—A-c. Exciter for a 6000-Kw. Adjustable-Ratio Frequency Converter

With the main motor running at exactly synchronous speed, the field of the a-c. exciter is stationary in space and direct current is taken from its commutator. Under this condition, the regulating machine furnishes direct current to the induction unit secondary, as required for the operation of the latter at synchronous speed. With the induction machine running above or below synchronous speed, the magnetic field revolves in space at a speed that is the difference between the speed with respect to the exciter rotor and the mechanical speed; that is, at the speed of slip. Therefore, the voltage on the commutator of the a-c. exciter and on the commutator of the regulating machine is always of the same frequency as the secondary voltage of the main induction unit.

### CONTROL OF REGULATING MACHINE VOLTAGE

Means of controlling the magnitude and phase angle of the voltage taken from the commutator of the regulating machine will next be discussed:

By reference to diagram of connections shown in Fig. 3, it will be noted that the regulating machine has two fields, one, the load field, and the other, the power factor field. Both of these fields are connected to brushes on the a-c. exciter commutator.

The load field of the regulating machine is connected to two sets of brushes on the a-c. exciter commutator, as shown in Fig. 3. By shifting these two sets of brushes in opposite directions, the brushes are permitted to span a greater or less number of commutator bars, thereby furnishing the means of obtaining variable voltage for exciting the load field of the regulating machine. This brush-shifting mechanism is motor-operated, so the brushes may be shifted either automatically, or by the operator. The movement of the brush-shifting on this exciter not only shifts the brushes to include more or less commutator bars but the two brush yokes are shifted in such a manner that the axis of the brushes is shifted.

The shift of axis changes the phase angle of the a-c. exciter commutator voltage. This compensates for the phase angle shift in the regulating machine load field excitation voltage which varies with change in slip frequency. This compensation is necessary in order that the phase angle of the voltage taken from the commutator of the regulating machine will not vary with change of excitation on its load field.

Power factor correction is furnished by the main induction machine supplying a quadrature component of voltage in its secondary circuit. This quadrature component is obtained from the armature of the regulating machine by exciting its power factor field from a third set of brushes located on the commutator of the a-c. exciter. See Fig. 3. This third set of brushes is stationary. The amount of excitation supplied to the power factor field is controlled by adjustment of the rheostat connected in the circuit. The power factor field of the regulating machine is connected Y. Due to the fact that voltage exists at all times across the stationary brushes on the commutator of the a-c. exciter, the power factor may be corrected or adjusted at a time when the main induction machine is operating at its natural slip, that is when zero voltage is impressed across the load field of the regulating machine.

By use of a series or so-called "bulging transformer," as shown in Fig. 3, automatic power-factor correction is obtained to compensate for the change in wattless kilovolt amperes that would ordinarily occur on the induction machine with change in load. The primary of this series transformer is connected in the primary circuit of the main induction machine and the secondary is connected in the a-c. exciter power supply circuit. This secondary winding introduces a voltage in the a-c. exciter circuit which varies with load on the main induction machine and is out of phase with the voltage obtained from the power supply.

### OPERATING CHARACTERISTICS

When the speed of the synchronous machine corresponds to the natural slip of the induction machine at the required torque, no voltage is required from the regulating machine. If the speed corresponds to any other than the natural slip, output is required from the regulating machine, as shown by Fig. 5. This figure shows the output of the regulating machine for different combinations of slip on the induction machine and unity power-factor load on the main induction unit. The ordinates are calibrated in two different ways, the scale at the right indicating the slip of the main induction machine, and the scale at the left indicating the 25-cycle system frequency, under the condition that the 60-cycle system frequency is constant at 60 cycles. Line *C D* shows the natural slip of the induction machine when operating non-regulating, *i. e.*, with zero voltage across the main induction motor collector rings. Limits of load and slip are given by line *A B*, which shows full output of the regulating machine operating as a motor. Line *E F* shows limits of operation when the regulating machine is operating full output as a generator. Lines drawn vertically on the chart indicate operation with constant kw. load transfer through the main set. Points on any such vertical line show how output on the regulating machine

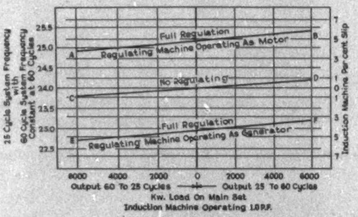

FIG. 5—OPERATING CHARACTERISTICS OF A 6000-KW. ADJUSTABLE-RATIO FREQUENCY CONVERTER

varies with change in slip, while kw. load on the main set is held constant. Lines drawn horizontally indicate operation with constant slip. Points on any such horizontal line show how output on the regulating machine varies with change in load on main set, while the relative frequencies on the two systems are held constant.

When the regulating machine is operating as a motor, the secondary power that would be lost in the resistor method, is transferred through the regulating set back into the line. When the regulating machine is operating as a generator, power is taken from the machine lines and transferred through the regulating set to the rotor of the induction machine.

### LOAD CONTROL

Load on the 6000-kw. adjustable-ratio frequency converter described may be held either by hand, or automatically. When under hand control, the operator changes load on the set by making use of a control switch on the switchboard panel. This control switch is connected to the small motor, which shifts the brushes on the a-c. exciter commutator. For automatic load control, a load relay is provided, which may be set to hold any load desired within the operating range. The load setting is changed by turning a small dial on the face of the relay.

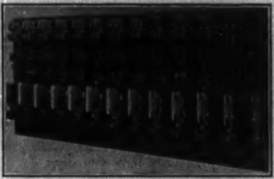

FIG. 6—AUTOMATIC CONTROL PANEL FOR A 6000-KW. ADJUSTABLE-RATIO FREQUENCY CONVERTER

The relay has a wattmeter element and a floating contact, which moves between two stationary contacts. If the frequency ratio changes to increase the load on the set above the relay setting, the relay contacts will close, and automatically shift the brushes on the a-c. exciter and bring the load back to the desired value. If the frequency changes to reduce the load on the set, the relay contacts close in the opposite direction, causing the a-c. exciter brushes to shift to bring the load back to normal again.

### STARTING

Control equipment is furnished which permits automatic starting of the set from the 25-cycle end. The operator starts the sequence of operation by merely pulling a control switch located on the switchboard. Fig. 6 shows the starting panel, with the contactors and relays furnished with one of the Rochester sets. The regulating set and then the main set is automatically brought up to speed. The main induction motor is started with the primary winding connected Y and is later changed over to delta connection. Resistors for starting purposes are automatically connected in the main induction motor secondary circuit, and are later cut out, a step at a time. To reduce the inrush of current to the induction machine and also to reduce the induced secondary voltage at starting, resistors are inserted in the primary circuit, momentarily. After both sets are up to speed, contactors connect the armature of the regulating machine to the rotor of the induction machine. By use of a control switch on the switchboard, the operator can then shift the brushes on the a-c. exciter, to change the speed of the set as required for synchronizing the 60-cycle generator with the 60-cycle system. After the synchronizing has been accomplished, load is transferred through the set in either direction, as desired, by either hand-control or automatic-load-control.

### PROTECTIVE FEATURES

Protective features are provided against a-c. undervoltage, over-speed, over-load, and excessive bearing temperature, and insure that the a-c. exciter commutator brushes are in the neutral position before starting.

The other 6000-kw. frequency-converter sets are very similar to the Rochester 6000-kw. set which has been described in considerable detail. The principal differences in the Altmar and Falconer 6000-kw. sets are their increased frequency range, and the provision for increased power-factor correction in the 25-cycle equipment. In the latter two sets the frequency range was increased 18 per cent, and the power factor of the main induction machine changed from unity to 95 per cent leading. In order to take care of this, the capacity of the regulating equipment was increased, the regulating machine itself being increased in capacity from 300 to 520 kilovolt amperes. With this arrangement, the 25-cycle induction machine can furnish leading current corresponding to approximately 2000 reactive kv-a. to the 25-cycle system over its entire load and frequency range.

The Devon 5000-kw. sets are different in several details from the 6000-kw. sets described. Ordinarily, it would be better to have the induction machine on the low-frequency end of the set, but in this case, a single-phase, 25-cycle machine was required, so it was necessary to place the induction machine on the 60-cycle end of the set. Also, in this case, the regulating machine is connected to the shaft of the main set, which makes an economical arrangement. Furthermore, on this unit provision is made for automatic power-factor control, as well as automatic load control, so the bulging transformers were omitted. Further simplification was made in the Devon sets by omitting the third set of stationary brushes on the commutator of the a-c. exciter, and exciting the power factor field of the regulating machine from one of the sets of movable brushes. Also, in this case, no resistor was furnished in the primary circuit of the main induction machine, because of the lower induced secondary voltage in this unit.

The regulating machines furnished with the 5000-kw. Devon sets have a capacity of 500-kv-a. which is almost as much as the capacity of the regulating machine furnished with the 6000-kw. Altmar sets. However, the Devon regulating equipment is not used for power-factor correction to any great extent but rather to provide an increased range in the frequency regulation.

The regulating equipment is designed to raise the power factor of the induction machine to 90 per cent lagging and to furnish sufficient frequency regulation that the frequency of each system may vary 3 per cent either way, the worse case being when one system is 3 per cent high and the other 3 per cent low.

The main units of the Devon sets have different pole and speed combinations than the main units of the 6000-kw. sets, although the sets in each case connect 60- and 25-cycle systems. With the 6000-kw. sets, the 25-cycle unit has four poles, the 60-cycle unit 10 poles, and the normal speed of the 60-cycle synchronous unit is 720 rev. per min. With the Devon sets, the 25-cycle unit has 6 poles, the 60-cycle unit 14 poles, and the normal speed of the 25-cycle synchronous machine is 500 rev. per min. The Devon set was designed for less speed principally because of the more economical construction of the single-phase, 25-cycle synchronous unit that could be used. This lower speed also permits a saving in the capacity of regulating equipment. The most economical speed for the main set, as far as the regulating equipment is concerned, is 300 rev. per min., because at this speed, the 25- and 60-cycle synchronous speeds coincide, and less regulating is required for frequency variations away from 25 and 60 cycles. However, for the 5000- and 6000-kw. sets, the main units were not designed for 300 rev. per min., because the saving in the cost of the regulating equipment would be more than offset by the increased cost of the main units.

## FIXED RATIO INDUCTION-SYNCHRONOUS TYPE

A paper[3] has been written which covers in much detail the design, theory, and operation of the fixed-ratio induction-synchronous type of set; therefore, only a very brief description will be given at this time.

Fig. 7 shows a diagram of connections for a 35,000-kw. set, which consists of an induction and a synchronous machine.

A portion of the power transfer is made through the shaft of the unit in the ordinary way and the remainder of the power transfer is made electromagnetically through the induction machine by connecting its stator to the 60-cycle system, and its rotor to the 25-cycle system.

The induction machine has 14 poles and therefore a synchronous speed at 60 cycles of 514 rev. per min. However, its rotor speed is held down to 300 rev. per min. by the synchronous unit, this giving 25 cycles slip frequency at the induction machine collector rings. The electrical output of the induction machine rotor is approximately 25/60 of its kw. rating and the mechanical output of its rotor to the shaft of the synchronous unit is approximately 35/60 of its kw. rating.

Full load may be transferred through the set in either direction with unity power factor input. The magnetizing current of the induction machine is supplied through its rotor from the synchronous machine, which is designed to furnish the necessary reactive kv-a. for this purpose.

FIG. 7—DIAGRAM OF CONNECTIONS FOR 35,000-KW. FIXED-RATIO INDUCTION-SYNCHRONOUS FREQUENCY CONVERTER

## APPLICATION

In discussing the application of the different frequency converters described, the synchronous-synchronous type will be used as a standard of comparison because this type is most widely used.

The induction-synchronous type of set has a rather limited field of application, being used principally to furnish power to small loads where the frequency required is different from the frequency of supply. Sets of this type in the smaller sizes are somewhat less expensive than sets of the synchronous-synchronous type but they have the disadvantage of poor efficiency and power factor. Furthermore, the induction machine cannot furnish leading current for power-factor correction, and the variation of frequency with change in load may be a handicap.

The fixed-ratio induction-synchronous type of frequency converter also has a limited field of application, its principal use being in large cities where synchronous converters supplied with a-c. power of two different frequencies are to be tied together on the d-c. side. With this type of set the two a-c. systems are tied together through the same magnetic field, therefore the tie functions practically as a cable tie, the only difference being that the impedance drop in the unit is somewhat higher than would ordinarily exist in a cable tie.

---

[3] *A 35,000 Kw. Induction Frequency Converter*, by O. E. Shirley, A. I. E. E. TRANS., 1924, Vol. XLIII, p. 1011.

With a synchronous-synchronous set each machine tends to maintain voltage on the system to which it is connected, and a sudden drop of voltage due to a short circuit on one system does not in the first instant affect the voltage on the other system. The same is true in the case of a sudden phase shift in the system voltage due to a sudden load change. In either case, before any shock on one system can affect the other system the shock must be transmitted through the shaft and this requires time.

On the other hand the fixed-ratio type of frequency converter transmits such a shock instantly and causes a change of voltage on one system to affect the voltage on the other. In other words, the fixed ratio frequency converter ties the magnitude and phase of both systems and acts instantly, while the synchronous-synchronous type ties the phase only and requires time.

With the synchronous-synchronous type of set, a large voltage drop on one system may occur without affecting for the moment the other system. With synchronous converters of the two systems paralleled on the d-c. end, this voltage difference would cause large currents through the converters inverting those on the low voltage system. The fixed ratio type, however, would function in much the same manner as a cable tie allowing parallel operation of the synchronous converters under severe conditions.

The synchronous-synchronous type of set has some operating disadvantages as compared with the adjustable ratio type of frequency converter, but in the majority of cases these operating disadvantages are not sufficient to warrant the purchase of a more expensive set using the adjustable frequency ratio principle. Operating experience shows that in the majority of cases interconnected systems may be so operated that systems of different frequencies may be connected together by synchronous-synchronous frequency converters with no great inconvenience. In case of a system disturbance or system trouble, it may be desirable to disconnect the two systems and in such cases reserve generators are usually available to pick up any load that is dropped. The adjustable ratio frequency converters have the advantage that they may ride through system disturbances with less need of disconnecting the two systems. However, in deciding on the type of set to use in a particular case, it is necessary to decide how much the advantages given by the adjustable frequency converter set are worth. In general, it may be said that sets of the synchronous-synchronous type meet the operating requirements sufficiently well and have the advantage of lower cost, higher efficiency, and simplicity.

Although it is the general practise to use frequency converter sets of the synchronous-synchronous type, nevertheless there are particular applications in which the cost of an adjustable ratio frequency converter may be warranted. Frequency converters of this type are well adapted to connect large central station power systems to industrial or railway systems where the industrial load or railway load may cause considerable frequency fluctuations. Another application would cover cases where the extra cost of the adjustable frequency ratio type will be warranted from the standpoint of being able to control the load at the set itself without need of making adjustments on prime mover governors.

### CHART RECORDS

Chart records given in Figs. 8 and 9 show how well frequency converter sets of the adjustable ratio type operate during system disturbances. The changes in voltage and frequency of both systems interconnected and the kilowatt load transferred through the frequency converter sets are given. The charts in question were taken at Rochester in connection with the 6000 kw. adjustable ratio frequency converter sets previously described.

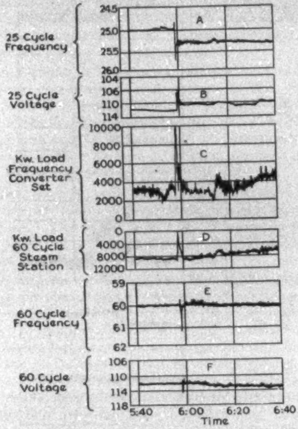

FIG. 8—CHART RECORDS OF A DISTURBANCE CAUSED BY SHORT-CIRCUIT ON 25-CYCLE SYSTEM

System tied to 60-cycle system by two 6000-kw. adjustable-ratio induction-synchronous frequency changers. Chart shows load on one set.

In each case the system disturbance was caused by a short circuit on the 25-cycle system. It will be noted that the short circuits caused a dip in 25-cycle frequency and that the clearing of the short circuits accompanied by load reduction caused an increase in 25-cycle frequency. In Fig. 8 the 25-cycle frequency changed from 25 cycles to approximately 25.3 cycles where it continued to operate. The 60-cycle frequency after a momentary swing, continued to operate at approximately 60 cycles. This change in frequency ratio clearly shows the advantage of an adjustable ratio frequency converter.

At the time of the disturbance shown in Fig. 8, the 6000-kw. frequency converter sets were transferring power from the 25- to the 60-cycle system, each carrying about 2500 kw. load (the chart shows only the load on one set). The increase in 25-cycle frequency to 25.3-cycles caused a sudden increase in power transferred through the sets as shown by 8-C. The sets were momentarily overloaded, the needle swinging to the end of the scale, showing the power exchanged was at least 10,000 kw. on each set. 8-C shows how the load relay operated and quickly reduced the load on the frequency converters back to normal.

8-D, 8-E, and 8-F show that the trouble originating on the 25-cycle system did not cause much disturbance on the 60-cycle system. The sudden increase in load on the frequency converter sets quickly reduced the load on the 60-cycle steam station as shown by 8-D.

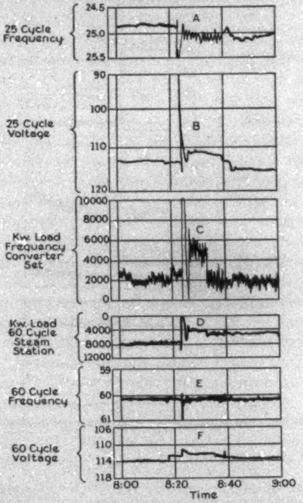

FIG. 9—CHART RECORDS OF A DISTURBANCE CAUSED BY A VERY SEVERE SHORT-CIRCUIT ON 25-CYCLE SYSTEM

System tied to 60-cycle system by two 6000-kw. adjustable-ratio induction-synchronous frequency changers. Chart shows load on one set

The disturbance recorded in Fig. 9 was much more severe than the disturbance recorded in Fig. 8. Here the 25-cycle voltage decreased momentarily to a very low value, the chart needle going off scale. In this case the 25-cycle frequency increased momentarily to approximately 25.5 cycles and remained at this high value for approximately 1½ min. As this large increase in 25-cycle frequency was out of the range for which the frequency converter was designed, the load relay and the load regulating device could not, during this period, reduce the overload on the set. This is shown by 9-C, the load through the set being such that the chart needle remained off scale until the 25-cycle frequency was again reduced. 9-D, 9-E, and 9-F show no great disturbance on the 60-cycle system during this period.

The fact that the adjustable ratio frequency converters rode through these disturbances as well as they did, speaks very well for their operation. The overload relays on the frequency converters were set for a little over double load. Therefore the disturbance recorded in Fig. 9 is about as severe a disturbance as the sets can handle without being tripped. It is very probable that a synchronous-synchronous set would have dropped out of step during the disturbances shown. With the synchronous-synchronous type of set a rise in 25-cycle frequency necessarily causes an equivalent rise in the 60-cycle frequency. Furthermore, during such system disturbances as shown, a synchronous-synchronous type of frequency converter would transfer more power through the set than a frequency converter of the adjustable ratio type.

## GOVERNOR CHARACTERISTICS

The amount of load that is passed through a frequency converter when load is dropped on one of the systems to which it is connected depends to a large extent upon the governor characteristics and speed regulation of the prime movers. The speed regulation of steam turbines is much less than the speed regulation of water turbines; therefore, where the interconnected systems are supplied principally from steam stations there will be less interchange of power through frequency converters during disturbances than would be the case if the systems were supplied with power from hydro stations.

The author wishes to express his appreciation for the cooperation given by E. K. Huntington of the Rochester Gas & Electric Co. regarding the chart records described, and acknowledge the general assistance given by Messrs. J. I. Hull, P. W. Robinson, and O. E. Shirley.

# Discussion

## INTERCONNECTION OF POWER AND RAILWAY TRACTION SYSTEM BY MEANS OF FREQUENCY CHANGERS

(ENCKE)

## APPLICATION OF LARGE FREQUENCY CHANGERS TO POWER SYSTEMS

(BURNHAM)

NEW HAVEN, CONN., MAY 10, 1928

**P. W. Robinson:** Referring to Table IIB the guaranteed full-load efficiency of 86.9 per cent given for the Devon set proved to be a very conservative figure. Tests of the apparatus as built showed overall efficiency at full load ranging from 90.08 to 89.22 per cent at operating conditions varying from no speed regulation to maximum regulation. A comparison of specified and test efficiencies is as follows:

| Load | ½ | 1 | 1½ |
|---|---|---|---|
| Specified | 80.3 | 86.9 | 88.0 |
| Test | 83.0 | 89.2 | 90.6 |

Referring to Fig. 1, Mr. Encke has for simplicity disregarded the effect of reactance and primary resistance of the induction motor. It may be of interest to mention an important effect of the reactance when power-factor improvement is required, namely that of increasing the amount of flux and consequently the magnitude of the induced secondary voltage. For example, if the natural full-load power factor of the induction motor is 85 per cent with 25 per cent reactive drop and the regulating machine improves the power factor to unity, approximately 14 per cent more voltage is required from the regulating machine assuming that the same speed regulation is maintained. This is the major factor in determining the increased size of regulating machine required for power-factor correction.

There is also an increase in the secondary current required for anything more than a few points power-factor improvement but this is usually of practically negligible amount unless leading power factor is required. When improvement on the leading side is effected the size of the induction motor is likely to be increased as well as that of the regulating machine because not only are the core loss and secondary copper loss increased but also the primary copper loss, instead of decreasing as it does up to unity power factor, increases again.

Another rather interesting effect of the reactance is that, as load is applied to the induction motor, it retards the phase of the voltage required from the regulating machine. This phase shift calls for a change in the phase of the exciting current of the regulating machine as the load is varied. This change is effected in the Devon set by use of the automatic power-factor rheostat as explained by Mr. Encke and in some previous sets by use of bulging transformer.

Mr. Encke has mentioned that the interpole winding of the Scherbius machine at Devon is connected only for below synchronous operation. In explanation of this fact it may be noted that the required amount of speed regulation below synchronism is considerably greater than that above due to the fact that the synchronous speeds of the two main units are different while the specified frequency variations above and below normal are equal. This interpole winding produces interpole flux to set up a rotating voltage in the commutated coils in opposition to the voltage induced in them by the alternating field flux. It was considered advisable in this case to supply such interpole excitation for the higher flux frequency below synchronism but it is not needed above and would complicate the switching to provide it as the connections must be reversed. The ordinary interpole excitation for current reversal like that used in d-c. machines is supplied by extra bars in the compensating winding. By these two means it is theoretically possible in this type of machine to balance all voltages tending to produce sparking at the brushes. As may be observed the practical results attained in this case are almost complete absence of sparking under working conditions.

Referring to the adjustable-ratio induction-synchronous type of converter, the ordinary systems of exciting the regulating machine do not provide a means of building up and stabilizing the voltage on the induction unit to supply power to a "dead" system. Special schemes for excitation may be provided if required to accomplish such results. Unless reduced output is required for such conditions the scheme used should preferably provide for supplying low-frequency excitation rather than direct current to the rotor of the induction unit so that evenly distributed heating will be secured.

**H. F. Brown:** The question has been asked, why tie in a 25-cycle system with another 25-cycle system through a flexible variable-ratio frequency-changer set? There are five important reasons why this was done in the case of Station A.

The value of power interconnections is too obvious to comment on further. In order to connect together two systems of quite different sizes, it is of course necessary with the synchronous-synchronous set to observe certain proportions in the rated size of the set. The variable-ratio frequency-changer set can be any size within the limits of the smaller system. That of course is the first reason.

The second reason is because a railroad load naturally has a ragged peak characteristic. By means of this type set the swings are entirely eliminated from the smaller station.

Further, a single-phase railroad load such as the New Haven Railroad has produces an unbalance in the three-phase system as between phases at heavy loads. Taking it through this type of a set eliminates that tendency.

The single-phase railroad load such as the New Haven, is also lower in power factor than a system such as Station A supplying converters. The power factor of the smaller system is not affected and may be, in fact, improved on both systems by the use of such a set.

The fifth and last reason is the fact of the ability to ride through system disturbances. When it is considered that any railroad system of the size of the New Haven, may be subject to a large number of short circuits or line disturbances in a month, it will be realized that this is an important consideration. It is no reflection on the railroad system to have these disturbances, and the ability to continue operation and ride through them is one of the most important matters that engineers at present have been giving their attention to. The fact that we are able to carry a heavy railroad load through disturbances of this kind shows how this feature has been entirely put in the background as far as electric railroad operation is concerned.

**O. E. Shirley:** The papers have brought out the fact that there are three types of frequency converters available to interconnect two systems. It is sometimes possible by a very preliminary survey to determine the most suitable type, while in some cases it may be necessary to consider difference in initial cost, efficiency, and operating characteristics in considerable detail.

The selection of the variable-ratio type for the New Haven Railway converters, which have been described in these papers, could be made with practically no consideration of the other types.

The comparison of the variable-ratio converter with the other two types in ability to continue operation after severe disturbances may be explained by an analogy of springs. The fixed-ratio type may be considered as a short stiff spring, which will offer a rapidly increasing resistance to variations in frequency of either system, and will break before allowing much displacement. The machine of the fixed-ratio frequency converter with the lower synchronizing torque will fall out of step when its maximum capacity is reached, and it will then be necessary to resynchronize.

The variable-ratio set on the other hand may be compared to a longer spring which will yield much more for the same force. Disturbances tending to cause variations of frequency on one system, will, therefore, not cause an excessive load transfer through the variable-ratio frequency converter, and the load control will very quickly bring the load back to normal after the trouble is over.

These papers have also brought out two different types of regulating machines, one direct-connected or geared to the main units, and the other driven by an induction or synchronous machine which may operate either as motor or generator. There is no general rule for the choice between these types and the one to be used for any particular case must be determined for the size and speed for that case.

**A. G. Oehler:** I should like to know if this type of variable-ratio frequency converter has the same ability to cushion shock occurring on either end of the load, that is, when the shock is transferred in either direction?

**L. W. Encke:** Mr. P. W. Robinson mentions that factory tests made on the Devon sets showed overall efficiencies higher than those mentioned in the paper. The efficiencies of both types of sets given in the paper are values set forth in the specifications. After the installation of the machines, efficiency tests, made by metering the input and the output of the whole set, gave for the Devon sets about the same results as those found on the test floor, and for the Station A machines efficiency figures equal to those on the Devon sets.

Answering Mr. A. G. Oehler's question, it can be said that this type of variable-ratio frequency changer cushions shock occurring on either system. Furthermore, immediately after the disturbance is over, the lead-regulating equipment restores normal load conditions on the set.

**E. J. Burnham:** In Mr. Robinson's discussion he mentioned the need of building up and stabilizing the voltage on the induction unit of variable ratio sets.

In supplying sets of this type we have always stated that sufficient generating power should at all times be connected to the induction unit to stabilize the frequency on the induction end of the set.

By referring to the diagram of connections it will be noted that excitation to the regulating machine comes through the a-c. exciter from the main line. Generating power should therefore be connected to the main line to furnish the required excitation. This generating power is needed to build up and stabilize the voltage on the induction unit when the set is started and it is also needed to stabilize the voltage and frequency during operation of the set.

At the Rochester Station, all the generating power was dropped from the 25-cycle induction end of the set momentarily to see if the set would hold its 25-cycle frequency, and it was found that the frequency did hold somewhat stable for a very brief time. I feel that it would not necessarily continue at this point of stability if dropping of load or fluctuations would take place on the system.

The variable-ratio type of sets now in operation have not been required to furnish power to a dead load from the induction unit; therefore special means of excitation to build up and stabilize the voltage on the induction unit have not been needed.

In case it should be required that the induction machine furnish power to a "dead" system, then special means of building up and stabilizing the voltage would be required. This could easily be furnished by use of a small motor-generator set which would furnish a-c. power at the desired frequency and voltage to the collector rings of the a-c. exciter.

Replying to Mr. Oehler's question, I might state that the variable-ratio type of frequency converter forms a flexible tie between the two systems so that shocks are cushioned as they pass through the set no matter which system receives the original shock.

# The Chicago Terminal Electrification
## of the Illinois Central Railroad

BY R. F. SCHUCHARDT[1] and W. M. VANDERSLUIS[2]
Fellow, A. I. E. E. Associate, A. I. E. E.

### INTRODUCTION

THE development of transportation, using the term in its generic sense, is a measure of the progress of civilization. This includes transportation of material things, as done by vehicles, ships, railroads, and air-ships; transportation of energy from hydro and steam generating stations to the user; transportation of thought by telephone, telegraph, and radio; and now, the transportation of views by television. Transportation reduces time and distance and increases man's range of activities. Communities thrive to the extent to which their transportation facilities are developed.

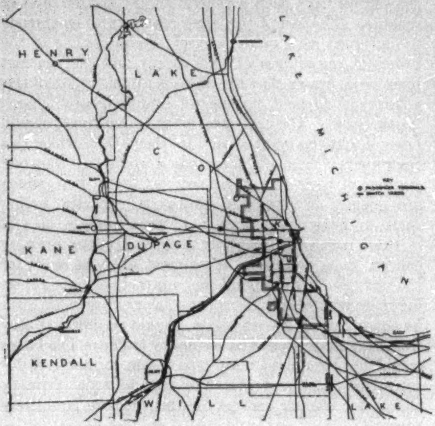

FIG. 1—RAILROADS IN CHICAGO REGION

Chicago enjoys the distinction of having the most extensive railroad facilities in the world. Its local street and elevated car systems are in the front ranks, as is also its electric power development; and its communication system is on a par with the best. This is not said in a spirit of boasting, but to give point to the statement that the methods used to solve the physical problems of that city are of interest to all progressive individuals, and particularly to engineers, since engineering is so much the basis of present-day progress.

In this is found our justification for accepting the invitation to present at this eastern Regional Meeting, a description and discussion of the first electrification of steam railroads to be put into service in the midwestern metropolis.

Let us first try to get a rough picture of the general local railroad situation. Downtown Chicago is served by 21 roads, though only 8 of these reach the central zone over their own track. (Fig. 1.) In the metropolitan area of 1750 sq. mi., there is a population of four million. There are 7726 mi. of railroad trackage and 4330 industries on railroad sidings. Six and one-quarter per cent of all freight in the United States (or 11,400 cars daily) are unloaded here and 4½ per cent are loaded. Nearly 35,000 freight cars are operated daily with a car mileage of over 1,150,000. An average of ten and one-half cars arrive, and the same number depart each minute.

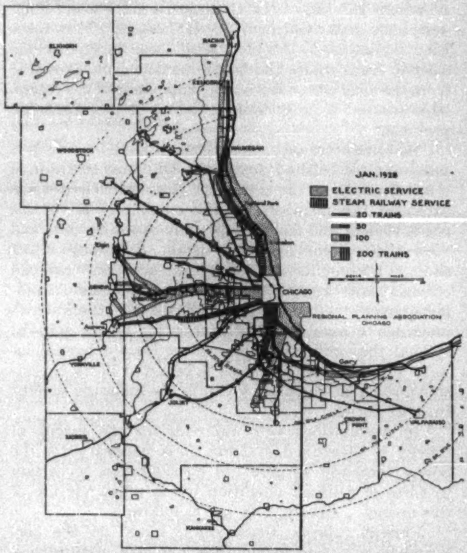

FIG 2—NUMBER OF RAILWAY COMMUTING TRAINS DAILY IN CHICAGO REGION—BOTH DIRECTIONS

In the passenger service, there are over 500 through trains carrying 45,000 passengers and about 1100 suburban trains, carrying 300,000 passengers, arriving and departing from the terminal stations daily. (Fig. 2.)

These figures[3] will help you to visualize the great system of transportation centering in the Chicago region.

---

[1] Elec. Engr., Commonwealth Edison Co.

[2] Elec. Engr., Illinois Central R. R., Chicago.

*Presented at the Northeastern District Meeting of the A. I. E. E., New Haven, Conn., May 9-12, 1928.*

[3] Freight data based on 1927 Report of the Committee on Coordination of Chicago Terminals, representing 28 roads. Passenger data estimated from 1923 survey data by same Committee.

With the continued growth of the city and the further expansion of railroad facilities, it seemed inevitable that some day many of the roads would be led to consider electrification of their terminal areas because of congestion, or for other compelling reasons. In anticipation of this time, and with a thorough appreciation of the economy to the community in having the necessary power supply taken from the existing central station system, in 1921 Mr. Samuel Insull, president of the Commonwealth Edison Company, appointed a committee to study the problem. It was Mr. Insull's desire that his engineers be well posted on railroad points of view and railroad operating requirements, so that in subsequent negotiations, the power men could better understand railroad language and railroad needs.

The Committee for the Study of Railroad Electrification, as it was called, was headed by Mr. Britton I. Budd, president of the Public Service Company of Northern Illinois, of the Chicago Rapid Transit Company, and of the Chicago, North Shore, and Milwaukee Electric Railroad. Its membership was drawn from the electric roads under the Insull management, as well as from the local electricity supply companies of the region. This insured a fuller understanding of transportation problems.

The committee met regularly each week for nearly a year, and also visited practically all of the steam road electrifications in the country. Greatest courtesy was extended the members by the officials of all of the roads visited, and facilities to study operating data and view the system in great detail, (including repair shops) were offered freely. In addition, railroad officials and representatives of equipment manufacturers were invited, and came to the committee's meetings to give valuable information on the subject.

That the committee obtained at least a partial insight into railroad problems is reflected in its conclusions, some of which are given in the following excerpt from its notes:

"In negotiations with railroads for the supply of energy to electrified systems, it is necessary for the power company to give full consideration to certain features of railroad operation which affect the use of this energy. Briefly, they are as follows:

"Present railroad operation is based on the performance of steam locomotives and will, naturally,—at least for the present,—be adhered to when a road is electrified. A steam locomotive is a self-contained unit and is not affected by the disability of other locomotives except as the track may be obstructed thereby. The total power available to the railroad at any time is therefore the sum total of all the locomotives in good condition. Train movements are thus limited only by the number of locomotives available and the track capacity. Electric service must approximate this condition as closely as possible. Energy to move trains as per schedule must at all times be available and interruptions very carefully guarded against. In emergencies, excessive amounts of energy may be required and the limit of the free capacity in station, lines, and substations should be available to the railroad.

"The contract should recognize the above requirements and should also express in its rates, terms, and conditions, the superiority of central station service from the railroad's point of view. The contract should reflect the fact that the cost of energy from a general power supply system is less than that from a properly designed separate station of the railroad, and that the service from such a general supply system is more reliable. The fact of the larger reservoir for emergency use afforded by a general supply system is one of the principal advantages of such supply and the contract must be so drawn that the railroad can make use of this advantage without paying an unduly heavy charge for such use. The railroads, on the other hand, should have it clearly pointed out to them that while this reservoir is very much larger than it would be if they had stations of their own, there are still limitations which are usually in line and substation capacity rather than in generating station. Excess reserve in any of these items will naturally require a larger primary charge, since additional investment must be made for the purpose. In drawing the contract, clauses covering emergency energy,—real operating emergencies, such as those caused by accidents, should be differentiated from those due to unusually heavy traffic. The latter would have required additional steam locomotives for the steam road, and therefore an additional primary charge for electric service for this purpose is entirely proper."

At the time of the committee's studies, the Illinois Central Railroad was solving its terminal electrification problem. These studies naturally were in the nature of preparedness steps, looking toward readiness to offer intelligently power service for such electrification, should an invitation for such offer be forthcoming, as it was later.

All members of the committee studiously avoided divulging their separate or collective thoughts with reference to a choice of system for this electrification. The power company stood squarely on the policy of readiness to serve the railroad with power in any form it desired. The contract conditions for the service would necessarily be affected by the choice, but not the willingness to serve. When the railroad made its decision for 1500 volts, direct current, and invited proposals for power supply on the basis of high-voltage energy, (the railroad to do its own converting), or on any other basis if desired by the power company, the latter submitted with its proposal for high-voltage energy, an alternate based on delivery of energy ready for traction use. It was felt that the road would be served better if all essential parts of the power supply were looked after by men especially trained for that work. This is also in harmony with the general interests of the community because of the better economy of joint use of part of the facilities for this and possible other electrifications and for light and general power service.

### THE ILLINOIS CENTRAL PROBLEM

The location of the Illinois Central tracks along the lake shore is not due to the railroad's wishes. It had no choice in the matter. When the city had grown large enough and wealthy enough to want the lake front for parks and boulevards, the railroad was in the way of these improvements, and it was necessary for some kind of an agreement to be reached between the city and the railroad company, involving the surrender of the company's riparian rights and an adjustment of other property in such a way that both the city and the railroad would benefit. For some years there was considerable agitation, also, in favor of the electrification of Illinois Central trains in order to eliminate the smoke which it was claimed detracted from the beauties of the lake front. An agreement was eventually reached between the city and the railroad by which all the desires of the city with regard to the improvements, particularly electrification, would be realized by stages, and by which the railroad, in turn, would receive certain benefits such as the acquisition of certain property rights and relief from the expense of protecting the lake front against erosion. This agreement is embodied in the so-called "Lake Front Ordinance."

On account of the diversity of ownership and of administrative powers of the various interests involved, it was necessary to make the agreement include the South Park Commissioners and also the Michigan Central Railroad. In addition, permission of the Secretary of War had to be obtained for certain of the lake front changes.

Under the ordinance, the railroad was obligated to electrify its complete suburban service by February 21, 1927. The electrification of the freight service north of Roosevelt Road must be completed by 1930, and south of Roosevelt Road by 1935. The electrification of the through passenger service must be accomplished by 1940, provided agreement is reached between the Illinois Central and its tenant railroads with respect to electrification.

The Illinois Central placed its suburban service in complete electric operation in July 1926, a full six months before the limit specified by the Lake Front Ordinance. In addition to the electrification, the railroad made many improvements, a large number of which were not required by the ordinance. These included extensive track changes, grade separations, yard construction, and other works.

The suburban service to be electrified was the most important means of rapid transportation serving the densely populated Hyde Park, Woodlawn, and South Shore districts, as well as the more outlying districts and suburbs directly south of the city. Because of its fast and frequent trains, it was considered the best transportation in the city, notwithstanding the fact that its coaches were old, small, and of wooden construction, and its locomotives equally small and old. The suburban system comprises 37.8 route miles, including 30 mi. on the main line and 8.8 mi. on two branches. There were three classes of trains; namely, local, express, and special. As many as six parallel tracks were necessary in the heavy traffic districts. In the year 1922, when definite plans for the electrification were begun, 21,500,000 revenue passengers were carried by these steam trains.

### SPECIAL COMMISSION APPOINTED TO STUDY THE PROBLEM

In order that this electrification might be along the most progressive lines, the railroad employed three noted electric railway engineers as an Electrification Commission to make an extensive detailed study of the requirements and a selection of the best system to fit these requirements. This Commission was aided by a staff of engineers employed by the railroad company for this purpose. In reaching its conclusion, the Electrification Commission made designs and estimates of the complete costs of electrification of the terminal by each of four different systems. Two years were consumed in this study, and in the autumn of 1921, the report was submitted recommending the 1500-volt d-c. system as the one best suited to this terminal electrification.

With the selection of this system, the Commission's work was ended. The railroad then gathered a force of engineers to design and construct the electrification. In the course of the design, numerous decisions had to be made, involving extensive studies and investigations.

### STUDIES OF THE POWER SUPPLY

Among the major studies that occupied the railroad's engineers was naturally that of the most satisfactory power supply, all things considered. Extensive and careful estimates were made to determine what the power costs would be if the railroad owned and operated its entire power system. These estimates were then compared with the proposals of the power company. In the decision, of course, these cost figures were fully considered, but the operating advantages of obtaining energy from a large centralized power system, and of having the power company perform the operations to provide the energy in the form needed for transportation service also carried weight. As a result of these studies, which were carried on over many months, the railroad concluded to purchase all of its electric energy from the power company.

### FUNDAMENTALS OF THE POWER CONTRACT

The contract which was entered into in 1924, and under which operations commenced in May 1926, calls for the delivery of energy from the substations of the power company. This is at 1500 volts, direct current, on the feeders of the railroad company for traction and 2300 volts, alternating current, for signaling. Three-phase energy at 4000 volts is also provided for the railroad's light and power requirements in its stations and shops. The present supply is taken from seven substations, five of which are within the city and two beyond the city limits (Fig. 3). From the two outside substations the power company supplies the energy by arrangement with the Public Service Company of Northern Illinois, which owns and operates these substations. This latter company, however, does not appear in the contract with the railroad company. The conversion equipment consists of synchronous converters and mercury arc rectifiers, which are described more fully below.

The charges for electricity follow the proved Hopkinson method with a "primary" in recognition of the power company's investment and a step rate "secondary" to cover the operating and service costs. In order that variations in coal cost may be taken into account, there is provision for a change in the secondary charges if the cost and heat content of the coal used falls outside of certain limits.

The primary charge is based on the maximum amount of electricity drawn under normal operating conditions. In order that the railroad company may have the advantage of the power company's large reservoir of power and without the payment of the regular primary charge for additions required in emergencies only, abnormal demands due to such emergencies are excluded in determining the maximum demand for billing. The recognized emergencies are:

1. Abnormally heavy traffic resulting from failure of other transportation lines, unless continuing for more than 10 consecutive days;
2. Traffic arising from extraordinary assemblages, such as fairs, race meets, ball games, conventions, and the like, unless continuing for more than 10 consecutive days;
3. Congestion of traffic arising from a railroad accident, derangement of power supply, or other emergency conditions;
4. Other excessive traffic beyond that usually carried and caused by some unusual circumstance or condition;
5. Hours during which the temperature is + 5 deg. fahr. or lower. (The suburban cars are all electrically heated.)

The limit to the amount of electricity which may be drawn under these emergencies is the capacity of the power company's equipment which may be usable for the railroad company's service during such emergencies. This is one of the features of the contract which makes the central station service of so much greater advantage to the railroad than would be that from its own separate plant. To insure a reasonable, continuing return on the investment made by the power company the railroad guarantees that the maximum demand that it will pay for in any month will not be less than 70 per cent of the highest demand established during the last preceding 12 months. A minimum monthly load factor of 30 per cent is also guaranteed.

Fig. 3—Electrification of Illinois Central Railroad (Showing Substation)

One of the railroad's requirements which was finally accepted by the power company but with some misgivings, relates to regulation of the feeder pressure. The high-speed suburban service with short intervals between trains requires a close adherence to running schedule and this, in turn, was felt to demand close voltage regulation. The permitted variation is from 1400 to 1550 volts on the feeders at the point of delivery at the railroad's right of way, which is practically at the substation feeder bus.

Provision is included for additional capacity in new or existing substations, as the increase in load requires. Of course, the power company may install additional equipment in its substations for uses other than this electrified railroad, and also use its equipment to serve other electrifications later if found advantageous to do so.

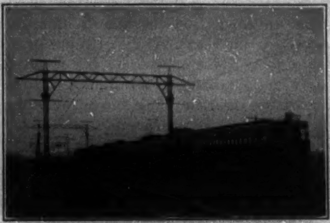

Fig. 4—8-Car Train and Catenary

## Description of Rolling Stock and Distribution System

The suburban cars of the electrified suburban service are of the most modern all-steel type of rapid transit cars, although considerably faster and heavier than the average subway and elevated car. They have been fully described in the technical press[4] at various times, so a detailed description here is unnecessary. All the trains are made up of standard two-car units, each unit consisting of a motor car and a trailer car semi-permanently coupled. In seating capacity and general appearance the trailer car is exactly the same as the motor car. The two-car units can be operated from either end. They reach speeds of 65 miles per hour on level track. They have a very fast acceleration and braking rate, which allows them to make short runs with high-schedule speeds. The express trains and the fast trains serving the outlying districts, however, make long high-speed non-stop runs until they reach the territory they serve.

The trains obtain their energy from the catenary distribution system. (Fig. 4.) The catenary over each electrified track contains four conductors, two of which are contact wires. It is directly connected to the feeder busses of the substations. The conductivity of this arrangement is such that no feeders other than the direct connections between substation bus and this overhead contact system are used. Normally the overhead system is all tied together through the substations and tie station buses (Fig. 5). These stations are so located that in case of faults, the section in which the fault occurs will be automatically isolated. High-speed circuit breakers with good selectivity characteristics are used in all connections. A detailed description of the distribution system can also be found in technical publications.

## The Substations and Their Equipment

The energy supply for the initial electrification is obtained through seven substations located adjacent to, or very near, the railroad right-of-way. Five of these are within the city and are fed from the generating stations at 12,000 volts, 60 cycles over the power company's cable system. The two substations in the suburban region are fed from the 33,000-volt, 60-cycle overhead transmission system of the Public Service Company of Northern Illinois. The line arrangement throughout is such as to provide reasonable reserve so as to insure a high order of reliability.

The major equipment installed in these substations is given in the Table. Figs. 6, 7, and 8 show the exterior of some of the substations.

The 1500 volts direct current for the traction service is derived in part through 3000-kw. synchronous converter units and, in part, through mercury arc rectifiers. Each converter unit consists of two 750-volt elements in series, together with a single-three-to-six-phase transformer. The illustration (Fig. 9) of a converter unit in the Brookdale Substation shows the flash suppressors around the commutator brushes. Another, and principal precaution against possible flashovers at the commutators is in the use of high-speed circuit breakers.

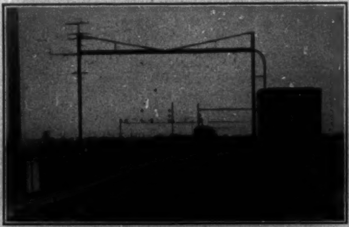

Fig. 5—Feeder Tie Station

The converters are designed to carry 150 per cent rated load for two hours and 300 per cent for one minute with satisfactory commutation. They are of the field-control type where d-c. voltage control is obtained by varying the excitation, thus regulating by means of the reactive current thereby produced.

[4] Quite fully in *General Electric Review*, April, 1927.

TABLE I
MAJOR SUBSTATION EQUIPMENT

| Substation | Synchronous converters |  | Rectifiers |  | Total kw. capacity | 1500-volt feeders |  | Light and power transformer capacity |
|---|---|---|---|---|---|---|---|---|
|  | No. | Rated kw. capacity | No. | Rated kw. capacity |  | Pos. | Neg. |  |
| E. 16th St. | 3 | 3,000 | 0 |  | 9,000 | 7 | 6 | 1,500 |
| Brookdale | 2 | 3,000 | 1 | 3,000 | 9,000 | 10 | 9 | 1,500 |
| Cheltenham | 2 | 3,000 | 0 |  | 6,000 | 4 | 2 | 150 |
| Front | 2 | 3,000 | 0 |  | 6,000 | 7 | 6 | 300 |
| Laflin | 0 |  | 1 | 1,500 | 1,500 | 2 | 1 | 75 |
| Harvey | 1 | 3,000 | 1 | 2,000 | 6,000 | 4 | 1 | 300 |
| Vollmer Rd. | 1 | 3,000 | 1 | 1,500 | 4,500 | 4 | 1 | 300 |
| Totals | 11 | 33,000 | 4 | 9,000 | 42,000 | 38 | 26 | 4,125 |

The exciter for each converter, mounted on the shaft of one element, is compound wound for constant voltage and the variation in the converter field voltage is automatically obtained by means of a counter e. m. f. regulating equipment. The converters are started from the a-c. side by means of the usual star-delta switches.

Fig. 6—16th Street Substation

A further means of voltage control is provided in the primary winding of the transformer. By means of interlocked oil switches, the connection may be changed under load from the full coil to a 5 per cent tap. Automatic reclosing is provided for the high-speed breaker on the negative lead of the converter with a time delay, which will reclose if the short circuit clears; but if it fails to clear, the positive breaker will also open. This, too, is of the high-speed type.

There are four rectifiers in this service, their location being shown in the table. Two of them, of 3000-kw. capacity, are of foreign manufacture and the other two, rated at 1500-kw. each, are of American make. Both of the 1500-kw. and the 3000-kw. units consist of two bowls each, operating in parallel. A single three-phase transformer with six-phase secondary windings feeds the pair of bowls of the 1500-kw. sets. The 3000-kw. sets are in effect, two 1500-kw. sets operated from one high-voltage switch. Each bowl has its own three-phase transformer. The secondaries are double six-phase connected to the twelve anodes of the bowl. (Figs. 10 and 11.)

These rectifiers are rated to carry 150 per cent load for 20 minutes and 300 per cent load momentarily (American units) or for one minute (foreign units). High-speed circuit breakers (Fig. 12) are provided on the d-c. side of these units. Special reactance coils connected in the neutral of the transformer secondary give the sets an inherent regulation of about 5 per cent. Corrective regulation is accomplished by hand-controlled tap changers on the transformer primary.

All of the 1500-volt feeders have a high-speed circuit breaker on their positive side.

In addition to this equipment for the traction service, each substation contains transformers with regulating and switching equipment for 4000/2300-volt, three-phase light and power circuits for the railroad and for 2300-volt signal service.

To insure safety and reliability, the substations contain a number of interesting features but a detailed description of these would belong to another paper.

## Operating Experience

This electrification has now been in operation for 21 months. From every point of view the equipment has met all expectations, and the complete operation has apparently been successful. The first electric time table was put into effect on August 28, 1926, with a total of 396 revenue trains. Today, 497 trains are being operated on a normal week day. There are 72 additional electric trains run by the Chicago South Shore and South Bend Railroad, which uses the Illinois Central electrified tracks between 116th Street and Randolph Street, making a total of 569 electric trains

Fig. 7—Brookdale Substation

on every week day. The public has shown its appreciation of the electrification by the increased traffic, even though the fares were raised 20 per cent a few months before electrification started.

Fig. 13 shows graphically the increase in revenue passengers from January 1924 to February 1928, and the effect of the electrification is plainly seen. On this graph are also shown the car miles, the seat miles, and the number of daily trains. It may be noted that the car miles did not increase very much after electrification, this being due to the fact that the seating capacity of the new electric car is one-third greater than the average old steam suburban car and the standing capacity is increased still more.

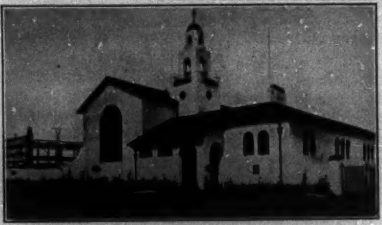

Fig. 8—Vollmer Road Substation

The operation has not been entirely free from troubles but that cannot be expected from an installation of the magnitude of this electrification. However, they have not been of a major character and with one or two exceptions, have not interfered with the transportation service.

Fig. 9—Synchronous Converters (Brookdale)

The operation of this service depends on an adequate and reliable supply of energy. While the Electric Service Agreement between the power company and the railroad company calls for a practically continuous supply of energy, both companies must at all times cooperate very fully in order to maintain efficient service, on account of the electric switching operations involved and because of common maintenance troubles inevitably arising. Such cooperation has been complete in every way, and all routine and emergency arrangements for continuity of service have been handled with efficiency and satisfaction.

Fig. 14 shows the magnitudes and variations of maximum power demand of this suburban service, the load factor, and the kw-hr. per car mile, all measured at the d-c. bus in the substations. The relation of these values to mean monthly temperature can be observed. The fact that the cars are heated entirely by electricity makes the temperature an important influence.

Fig. 10—Mercury Arc Rectifiers (Laflin)

Because of the heavy load fluctuations imposed on the substation converting equipment and of the close regulation specified by the railroad, there was doubt in some quarters that synchronous converters would give satisfactory service and motor generators were suggested. Fortunately these doubts have proved groundless, the performance of the converters having come fully up to requirements.

Fig. 11—Mercury Arc Rectifiers (Brookdale)

The rectifiers also, in general, have performed well,—particularly those of foreign manufacture. In the others, some improvements are still desirable and it is hoped that our American manufacturers will not permit themselves to be outdone for long. Because of the higher efficiency of rectifiers, they are naturally kept on the service for the long hour load. The close regulation is performed by the synchronous converters. As already stated, the exacting regulation specified has been met satisfactorily.

Fig. 12—High-Speed Circuit Breaker (with Asbestos Chute Tilted Back)

That very important link, without which the major equipment would not perform so satisfactorily,—namely, the high-speed circuit breaker,—has done all that was expected of it. Both in correct selectiveness and in effective current interruption its behavior has been excellent. The duty on these devices is at times heavy. They have effectively limited to a negligible degree the damage resulting from accidental short circuits in overhead wires or rolling stock.

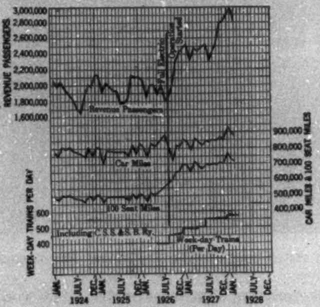

Fig. 13—Traffic Data

## POWER DATA

The maximum demand of the electrified road on the power system has thus far been approximately 24,000 kw. The total 1927 energy use was slightly under 59,000,000 kw-hr. The annual load factor was thus about 28 per cent. The monthly load factor varied from 32½ per cent to over 39 per cent.

At the time of the power companies' maximum load this last winter, the railroad's load was about 7 per cent lower than it was at the time of its maximum, which occurred a week earlier. It should be noted that this diversity existed even though the portion of the road thus far electrified—suburban service, only, in winter has a daily load characteristic which closely approximates that of the power company. With the addition of the freight and of the through passenger service, this diversity should be much higher.

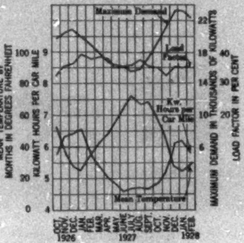

Fig. 14—Power Data

The increased business that the railroad has enjoyed since electric operation was begun has shown the inadequacy of the estimates originally made with reference to probable power requirements when the other branches of its service are added. The revised estimates have not yet been completed.

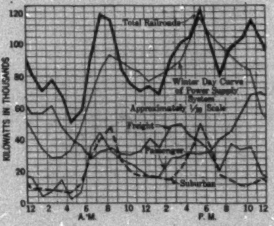

Fig. 15—Estimated Load Curve for 1928 for all Railroads in Chicago Assuming them to be Completely Electrified

The power company has made some rough estimates with reference to the entire Chicago railroad service, which are given in Fig. 15. This shows the shape of the daily load curve for a winter day. Superimposed on these curves is a typical curve of the regional power system load (but to a different scale). The combined railroad load is estimated to have an annual load factor of about 62 per cent. Further improvement may be possible by shifting freight time tables. From the power company's point of view, this is a very desirable load. The railroads, on their part, receiving their supply from the large power pool, would enjoy, among other things, the advantages of the high generating efficiency of the rapidly growing system, the comparatively large reserve, and the absence of heavy capital requirements for power purposes.

The estimated maximum demand for 1928 for all the railroads in the Chicago region, were they electrified, is on the order of 125,000 kw. This is but a little over 8 per cent of the interconnected generating capacity of the region; actually less than the single item of reserve normally carried by the power companies. Two points are brought out by these figures: (a) that the investment necessary to provide the power requirements of electrified railroad business is not a burdensome item in the power company's budget, and (b) that the particular form of energy required by the railroad will not have any appreciable influence on the general engineering plan of the power company.

While these conclusions are based on the conditions existing in the Chicago region, they will probably be found to apply with at least equal force elsewhere. The ever enlarging area being covered by substantial power systems with their far flung transmissions is constantly increasing the ease of obtaining a suitable supply of energy for railroad electrifications, as the railroads find, with the progress of time, that economic or other conditions make electrification desirable. Power systems will serve the railroads most effectively when there is a willingness to serve in the manner demanded so that the railroads in turn can produce their service as best suits the requirements of good transportation.

## Discussion

**E. R. Hill:** One of the very interesting and important features of the Illinois Central Electrification, as described in this paper, is the contract for the supply of power between the Railroad and the Commonwealth Edison Company. Probably the most unusual feature of this contract is the supply by the power company of converted current at the seven substations located along the railroad. It is more usual for the power company to supply alternating current at a single point and for the railroad to transmit and convert or transform this power itself.

The paper calls attention to the practise which has now become quite general, and which is regarded as absolutely essential in connection with railroad electrification work, for the power company to supply excess demands in railroad emergencies without affecting the demand charge. In other words, the demand charge is determined by the road's power requirements under normal conditions, and emergency drafts of power do not affect the demand billing. This is very important and really essential in connection with railroad operation because of the fact that abnormal and emergency conditions occur much more frequently in railroad operation than in probably any other industry, and it is impossible for the road to control or prevent the occurrence of such exceptional demands.

The most recent large power contract for railroad operation that the writer has knowledge of was negotiated and consummated last year between the Pennsylvania Railroad Company and the Philadelphia Electric Company at Philadelphia. This is a continuation and enlargement of an earlier contract covering the supply for the Pennsylvania Railroad's suburban service in Philadelphia, intended to provide for all traction requirements in that territory including through electrification between New York and Washington and elsewhere, if and when carried out, for a period of 20 years.

The power company contracts to supply the power at 25 cycles single-phase 13,200 volts at certain main supply points in the vicinity of Philadelphia or elsewhere as may be arranged from time to time. The railroad steps up the voltage to 132,000 and transmits at this pressure to its various transformer stations along the railroad.

The outstanding new feature of this power agreement is that the charges or rates are based on the actual cost to the power company of producing power in its generating stations, and of transmitting it to and converting it at the supply points. This actual cost, of course, includes fixed charges, general expenses, and all other items properly entering into the total cost.

In order that the railroad may be protected against any unforeseen high cost of producing power, the power company guarantees that the demand charge and the energy charge shall not exceed certain stipulated values that were estimated and set up at the time of the negotiations. Such guarantees are based on specific cost of coal and labor. Maximum rates for fixed charges are also stipulated.

Some of the other main features of the contract are:

Demand determined monthly based on three maximum normal clock hours per month.

Abnormal demands resulting from accidents, derangement of power supply, abnormally heavy traffic, or severe weather conditions, shall be disregarded in determining the maximum demand.

Demand may not be less than 75 per cent of any previous maximum demand.

Guaranteed monthly load factor is 30 per cent.

Guaranteed power factor is 55 per cent.

If lower rates are subsequently made to other consumers under similar conditions of supply, the railroad shall be entitled to the same rates.

At an average monthly load factor of 62 per cent, a coal cost of $5.00 per net ton, present labor rates, and guaranteed maximum demand and energy costs, the average cost to the railroad at the supply point or points under this contract works out 0.75 cent per kw-hr.

**Sidney Withington:** The question of power supply for railroad electrification is one not only of economy, but of reliability. These two important considerations do not necessarily go hand in hand; in fact, it often happens that a balance or compromise between them is necessary. For instance, it may be more economical to develop a single central supply of power for a given electrification project than to provide several sources of feed, but a single supply may mean that power-transmission facilities must be installed along the railroad right-of-way in close proximity to the tracks, with consequent danger of interruption on account of derailments. The right-of-way, furthermore, often passes through thickly settled communities where the clearance is restricted and where danger of trouble from a possible fire on adjacent property is considerable. Any hazard which results in cutting the power line in two obviously is going to be serious if it results in a complete prostration of service beyond the break.

As an alternative to a single point of supply there may be considered a main or central feed to serve as a "back bone," with supply points of relatively less capacity near each end of the electrified zone, so arranged that in the event of a failure of the main supply or a break in the transmission facilities the auxiliary source, may carry at least a portion of the load and thus take care of the most important service until normal conditions are resumed. Such an arrangement obviously costs somewhat more than a complete concentration, but the resulting increase in reliability is often worth the added cost in an important electrification project.

A third possibility which may sometimes be practicable is the tying at various points to a single large power system with a transmission network entirely independent of the right-of-way of the railroad. Such a system is often fed from two or more independent power plants or interconnected with other power systems. In an arrangement of this kind any single interruption of power or transmission would normally not seriously affect railroad operation. If conditions are favorable, such an arrangement is from many points of view quite ideal, for it allows advantage to be taken of the maximum railroad load factor with consequent minimum cost, and at the same time obviously produces maximum reliability. The choice of power supply in any given instance obviously depends upon local conditions and facilities readily available.

Although in many instances a generated frequency of 25 cycles is available commercially which makes possible a tie directly into railroad traction feeders, the power available from a large commercial system, is usually 60-cycle three-phase, and is thus often not adapted for direct supply without modification for heavy electric traction, and therefore, regardless of the system of electrification, some form of conversion apparatus is generally necessary if power is purchased. If a railroad produces its own power the characteristics of the power supply of course are correlated with those of the system adopted.

The two electrification systems of power distribution most often employed in this country are (2) direct-current, operated at various voltages from 600 to 3000, and (1) alternating-current single-phase usually operated at 25 cycles and 11,000 volts. To adapt three-phase 60-cycle power from a commercial 60-cycle supply to either of these systems requires some form of substation apparatus, which in the case of direct current may be mercury-arc rectifiers, motor generators, or rotary converters, and in the case of single-phase takes the form of motor-generator frequency changers.

Other things being equal, the purchase of power by a railroad for traction purposes should be more satisfactory than the operation by the railroad of its own plant. The capital requirements for railroad electrification are necessarily very high at best. The cost of power distribution facilities required to convey power to the collecting devices of the motive-power units runs into many thousands of dollars for each mile of track electrified. The acquiring of locomotives or cars on an equipment trust allows postponement to some extent of a portion of the immediate capital requirements, but the purchase of power will eliminate the relatively large capital which would be necessary for its own power-plant installation.

It is, however, necessary that power companies which are interested in supplying power for railroad electrification shall consider all the aspects of the questions, such as diversity of load compared with other customers (for much of the railroad load, especially freight, occurs during the night), and the volume of business involved.

With growing efficiency of power-plant apparatus made possible, especially by concentration in large units, it is logical to expect that the production of power by organizations specializing in such production would be more economical than production by railroads themselves, provided, however, that such economies are not obtained at the expense of too high investment charges, so that the consumer does not have the benefit. It should be borne in mind in this connection, also, that railroads are often in a position to purchase coal more advantageously than power companies.

Railroads do not as a rule pay as high a rate of interest on capital investment as do power companies, and this should be taken into account in determining the demand or primary charge which represents the cost of the money invested in plant and associated facilities. If a railroad installs its own plant, it may justly contemplate calling upon its reserve capacity for such emergencies as may sometimes occur in the course of its operation; and a power company in taking on a railroad power supply should be prepared to carry the load, during abnormal conditions over which the railroad often has no control, without subjecting the railroad to penalty in establishing demands. As has been pointed out by Messrs. Schuchardt and Hill, most of the important agreements for power for railroad traction purposes now recognize this important point, to the mutual advantage of all concerned.

The early New Haven electrification, inaugurated in 1906, was originally supplied from a railroad-owned power plant located at Cos Cob, Conn., which is not far from the center of the system load between New York and New Haven. Commercial power at that time was not available. The Cos Cob Plant, with a capacity of about 13,000 kw., served the initial installation between New York and Stamford. In 1912 the plant was enlarged to about 32,000 kw. capacity to carry the New York, Westchester & Boston and the Harlem River Branch freight traffic and the electrification through to New Haven which was inauguarated in 1914.

In 1915 there was added to the power system a supply from the United Electric Light & Power Company at West Farms, N. Y., the power being generated at the Sherman Creek Power Plant of that company. This connection is supplied from turbo generators used exclusively for railroad service, and although the power company's machines share with Cos Cob the power swings, nevertheless with proper supervision considerable accuracy in the control of load and consequent supply of energy is possible.

With the growing load on the New Haven the question of a power supply at the east end of the electric zone was considered. The alternatives were (1) concentration at Cos Cob with independent high-voltage transmission and step-down substation at the east end of the zone, and (2) entirely independent supply at the east end, somewhat analogous to the West Farms supply. The result was a decision in favor of independent supply and the installation at Devon, Conn., of two 5000-kw. (continuous) frequency-changers for the purchase of power from the Connecticut Light & Power Company, and at New Haven of one machine of similar capacity for interchange in either direction of surplus power with the Connecticut Company.[1] These facilities automatically allow continuous or definite control of load as desired, regardless of relative variations of voltage, load, or frequency in any of the systems involved.

An extension of the New Haven System over the New York Connecting Railroad and on the Long Island Railroad to Bay Ridge, N. Y., made desirable a connection with the Pennsylvania Railroad power system at East New York which could be used in emergency. A motor generator similar to that at New Haven was thus installed at that point. That motor generator, as well as all of the other apparatus of that type, is available as a synchronous condenser to maintain a favorable power factor. There are thus now in service on the New Haven System five points of supply: East New York, West Farms, Cos Cob, Devon, and New Haven.

There is no doubt that the concentration of power at Cos Cob would have been more economical than the policy of decentralization which has been adopted, but the consideration of reliability justifies the extra expense. While Cos Cob is the main source of supply, the auxiliary sources are of sufficient capacity in the event of an emergency to provide the continuance of at least the more important traffic, and it is our opinion that there is a satisfactory balance between the two important considerations, economy and reliability.

---

[1] *Interconnection of Power and Railway Traction Systems by Means of Frequency Changers*, by L. Encke, see p. 1056.

**G. I. Wright:** I want to make a few remarks about the economic aspects of such a service as the electrified Illinois Central, and these in general will apply to any suburban or commuter service for passenger traffic for a large city.

The handling of such a business is not particularly attractive from an economic standpoint, but although passenger revenues and passenger business for the railroads as a whole are falling off, yet suburban business is either holding its own or in most cases increasing.

The paper states that the load from the power company's standpoint is a favorable one, and I presume it means economically favorable. Suburban passenger business from a railroad standpoint is in general not economically favorable, and one of the most interesting things in connection with the electrification of such a service is its effect upon the net return. This business is a low-load-factor business; actually the ratio of the average number of passengers hauled to the maximum number hauled during rush hours is around 25 or 30 per cent. This means that the rolling stock and the total investment in railroad facilities necessary to handle the business is largely idle during the greater portion of the day.

A power company in selling electricity gets a return on a low-load-factor business by having a rate which takes into account the maximum demand. I believe the fact that their rates bring them a return for the service rendered and the investment necessary to handle that service is largely responsible for the growth and success of the power companies in this country.

With a railroad handling commuters this is not so. The rate for passengers who ride during the rush hour is very much lower than the rate for a ticket to ride during any part of the day. The latter have to pay 3.6 cents a mile. The rate for the commuter, in the case of the Illinois Central, is as low as 0.6 cent a mile. This means that for this low-load-factor business they are getting a very low unit price.

I do not believe that power people who are accustomed to their unit rates varying with the load factor of the load realize what the railroads are up against from the standpoint of economically getting a return on the service rendered. The railroads have probably not done as much to correct this condition as the power companies have. The power companies have insisted on a rate which takes into account the load factor. They have also given off-peak rates and have constructively gone at the problem of building up their load factor and increasing the off-peak business. The railroads under steam operating conditions have done very little. After electrification it is possible to make improvements in this respect. You can operate economically shorter trains and more frequent train service during the middle of the day and thus make a bid for that business as has been done by the Illinois Central. The cost of fuel for steam operation is the same no matter what time of day it is burned in the locomotive, while the cost to the railroad of electric current used during the non-rush hours is only a fraction of the cost if used during the rush hours, as it does not increase the power company's investment or the demand charge which brings them the return for this investment.

The Illinois Central's electrified service with its faster schedules and greatly increased frequency of train service in the non-rush hours, has not only attracted new residents to the territory served but has increased the riding habit of those already there. The Sunday business has also been greatly increased by this method. The Illinois Central has also put into effect a reduced round-trip rate of a fare and a half and has made a bid for the business of those who would hesitate to pay 3.6 cents a mile to make a trip down town. I believe they could well afford to have made this rate still lower.

It must be highly gratifying to the management that they have been able to turn a large operating loss into an operating profit sufficient to pay some return on the increased investment, and this with lower rates than are charged for most similar services. This fact should also be of interest to the management of other railroads who have not as yet electrified their suburban services.

**H. C. Sutton:** Most electrifications in the East have been for suburban service. A factor that is very interesting to the central stations is that with the extension of the electrifications to take in trunk-line railroads, the load factor of 26 to 30 per cent which is now obtained on suburban service, will be increased to a load factor of over 60 per cent with combined suburban and trunk-line electrification.

A study is being made of the electrification of an important railroad in the East where the peak load occurs in the early morning hours, due to the schedule of getting the trains into the metropolitan terminal early in the morning. This should result in a high diversity factor for the central station for this type of load.

There are some reasons why purchase of central-station power should prove of benefit to the railway, which have not been brought out in the papers. Take, for instance, the cost of supplying service by the central station as compared with the cost of the railway company's putting in its own generating station. If the railway furnishes its own supply it would have to build a plant at considerable expense, namely, a modern plant of the day in which it is designed and built. However, past history would indicate that in a ten-year period that plant would be relatively uneconomical as compared with plants built at later dates. Under central-station supply additions to the generating capacity are continually made to take care of the rapidly growing load, where in many locations the load doubles in five- or six-year periods. Central stations, therefore, are continually building new and better plants with an advance in higher efficiency, with the use of larger turbine units, etc., bringing down the cost of power from year to year. The railway company, therefore, should benefit in future readjustment in rates when based on the cost of supply.

There is another interesting fact in regard to suburban railway electrification and that is the rate of the growth of traffic is greater than prior to the electrification due to the greater ease and comfort in riding on the electric trains.

**O. K. Marti:** I was very much interested in the paper by Messrs. Schuchardt and Vandersluis, especially since mention is made in it of the new converting equipment used, the mercury arc rectifier. This is the first main-line electrification with such devices in this country. Further, because of its peculiar operating conditions, this line imposes very high duties on the converting equipment, and it was therefore very interesting to learn more about the operation of the rectifiers.

As we all know, rectifiers have a very high efficiency at high voltages. The efficiency at 1500 volts is much higher than that of any other converting device. Since rectifiers for 2400 and even 3000 volts are just as satisfactory in operation, it would be interesting to learn whether Mr. Schuchardt could give any information as to the possibility of operating such a railroad as the Illinois Central at these higher voltages.

Another thing which I should like to bring out, and on which I should like to hear some comments, especially from railroad engineers, is whether a higher voltage drop on the trolley wires would not be permissible, and whether this would not be more economical from many points of view. Thus far compounding windings have always been used on old converting equipment, and other means as well have been employed to keep the voltage as constant as possible.

During the discussion of this paper Mr. Wright mentioned that a high load factor allows a smaller unit to be used for converting alternating to direct current, and is therefore very desirable. It seems to me that by allowing a high voltage drop in the machine we would get a still better utilization of the units, especially if the converting devices are distributed along the system instead of being concentrated in one place.

This directly relates to the question of the location and spacing of substations, namely, should rectifiers be grouped in substations of comparatively large capacity or would it be more economical and advisable to locate them along the railroad line, distributed in smaller stations. An extensive railroad system which is at present being electrified is the Berlin Rapid Transit, which consists in part of a belt line uniting all the suburbs of Berlin. In this system the rectifiers are spaced very closely, and are located in the existing structure, in this case in the arches of the elevated structure supporting the tracks of the railroad.

**P. H. Hatch:** Electrification has been so far tied up intimately with power supply. In the future, it seems to me, we should consider the effect of independently propelled locomotives similar to, and having the advantages of, the electric locomotive but without the complications of the distribution system. I refer to the Diesel electric locomotive or the straight Diesel unit. It promises the combined advantages of the electric equipment. In the future what effect will this have on our power requirements?

Another problem is the question of standardization of frequency for railroad power supply. Those of us who are using the 25-cycle single-phase system are wondering if 60 cycles becomes standard what we will do for power conversion. Will we have to supply rotating machinery for converting our power? If such is the case, then some of the advantages of a-c. electrification in this country may not be entirely realized.

**R. F. Schuchardt:** The question Mr. Marti has asked me should have been asked of Mr. Vandersluis since it involves the railroad's choice of electrical system. Mr. Vandersluis will probably, however, agree with me that to go into this question at all would be to open up the entire subject of systems for railroad electrification, which is quite beyond the purpose of this meeting. However, it might be worth while to point out to Mr. Marti that among the deciding factors in the selection of trolley voltage, the efficiency of the substation equipment is not a paramount one.

**W. M. Vandersluis:** Our paper was prepared especially to bring to the attention of the power companies the necessity of studying the power needs of steam railroads contemplating electrification and meeting those needs squarely in offering their services. That the railroad requirements are different has been clearly brought out in the paper and in the discussion.

The agreement in question, covering service to an electrified steam railroad at seven different points and with all the required feeders to the right-of-way line, is the first of its kind. Naturally, it was entered into by the railroad company with some misgivings at times as to how it would work out. The length of the agreement so indicates, although it would have been much simpler if left entirely to the engineers of the two organizations.

It has been in operation for over two years and so far nothing has come up to indicate the necessity of any particular change in its various clauses. This is due not so much to the wording of the agreement as to the spirit of cooperation evidenced, we believe, by both parties in their desire to understand and meet the service requirements of each.

Power companies contemplating similar services to electrified steam railroads can profit by the attitude of the companies in question and the results obtained.

# Effect of Street Railway Mercury Arc Rectifiers
## On Communication Circuits

BY CHARLES J. DALY[1]
Associate, A. I. E. E.

***Synopsis.**—This paper describes the effects experienced on the telephone circuits from the two mercury arc rectifier substations recently installed in Bridgeport, Conn., and shows in table form the relative magnitude of the interfering effects between rotating equipment and mercury arc rectifiers as a means of energizing the street railway system. The method and the type of apparatus used to reduce the effects experienced from the rectifiers are also described.*

* * * * *

THE application of the mercury arc rectifier for supplying power to street railway systems is now attracting a great deal of attention. In considering such an installation the question naturally arises as to its effect on communication circuits. In December 1927 all the current for the operation of the street railway system serving the territory in and around Bridgeport, Conn., was obtained for the first time from two mercury arc rectifier substations. A comparison of the relative interfering effects on the telephone circuits between this method and the previous method used for energizing this railway system was obtained and is described in this paper.

Both substations were not placed in operation at the same time, there being an interval of about four months between the installation of the larger station at Bridgeport and that of the smaller at Stratford. During this interval the larger rectifier station was operating in parallel with the rotating equipment of the old generating station for a short period of time only. Measurements of the interfering effect of the noise experienced on the various types of local telephone circuits were made just prior to the placing in service of the first rectifier station and immediately after each substation was connected on the line, as well as after temporary remedial measures were applied. The measurements obtained under these various conditions of energizing the railway system are shown in the accompanying tables.

### TYPE OF TELEPHONE PLANT

The Bridgeport exchange is a multi-office area served by three sub-offices, two of which are in the same building located in the business center of the city within one-quarter of a mile of the larger rectifier substation. The third sub-office is located in Stratford, approximately four miles from the Bridgeport central office building and within a quarter of a mile of the smaller rectifier substation. The interoffice trunk circuits connecting the Stratford telephone office with the Bridgeport main telephone offices are in underground lead-covered paper-insulated cables and with the exception of about one-half mile are parallel to and in the same streets with the railway system. See Fig. 1.

All subscriber telephone circuits on the same streets with the railway circuits are in lead-covered cables or twisted pair wire. The greater portion of the cable plant is in underground construction, although there are several relatively long runs where the cables are on poles jointly occupied with street railway circuits, and in a few instances on the same poles with both positive and negative railway feeders. There are no open-wire telephone circuits on the same streets with the street railway circuits.

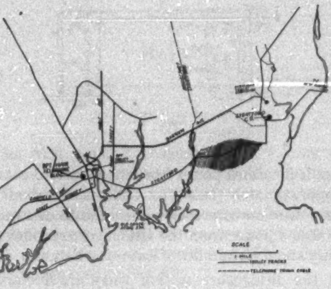

Fig. 1

The types of telephone service provided include standard individual line service on which metallic ringing is used, standard two-party selective and four-party semi-selective service, and private-branch-exchange service. In the selective service both the two-party and the four-party semi-selective types are provided.

It might be well to describe in some detail the signaling circuit used with the selective type of service. Fig. 2 shows the schematic wiring for a two-party selective circuit. It can be seen that each side of the telephone circuit is connected through a condenser, usually of 1 $\mu$ f. capacity, and then a ringer to ground. The ringer has a d-c. resistance of at least 1000 ohms and an impedance at 800 cycles of over 30,000 ohms.

---

*Presented at the Northeastern District No. 1 Meeting of the A. I. E. E., New Haven, Conn., May 9-12, 1928.*

[1] Transmission and Protection Engineer, Southern New England Telephone Co.

This connection to ground is used only for ringing purposes and not for transmitting the voice frequencies, as may be judged from the impedance in the ringing circuit to ground. With this arrangement the bell at one station can be rung independently of the one on the other side of the circuit.

The four-party semi-selective service is similar to the two-party service described above except that two stations are connected to each side of the circuit. With this arrangement, however, both bells on the same side of the line are rung when the ringing current is imposed on that particular side of the circuit. In the case of the individual-line service, signaling is obtained on an all-metallic basis by bridging the bell circuit across the telephone line.

### STREET RAILWAY SYSTEM

The street railway system consists for the most part of a double-track system with the rails and earth, supplemented along some of the routes with negative feeders, as the return circuit. Fig. 1 shows the railway system within the Bridgeport and Stratford city limits and the relative locations of the two rectifier substations. An interurban line extending to New Haven is furnished power from the Stratford substation for approximately half the distance or about seven miles. Another interurban line runs to Norwalk and is furnished power from the Bridgeport rectifier station for only about eight miles of its entire distance.

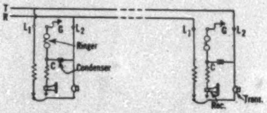

FIG. 2

At the Bridgeport station there are five six-phase rectifiers which are energized from a 13,900-volt, three-phase, 60-cycle power line and deliver 600 volts direct current to the street railway system. Each rectifier is rated for 2000 amperes. Two similar type rectifiers are in the Stratford substation operating under the same conditions and in parallel with the Bridgeport station.

At the time of the writing of this paper a temporary filter had been installed in the street railway circuit in the Stratford rectifier station, but none had been installed at the Bridgeport rectifier station, although permanent filters were in the process of manufacture for both stations.

### METHOD OF MAKING MEASUREMENTS

In order to determine the interfering effect experienced by the telephone subscriber under normal operating conditions, all measurements were made from the receiver terminals of the telephone instrument with the circuit connected through the switchboard to another telephone set located in the central office building. Measurements were obtained for various conditions that would be found in the practical operation of the telephone system. Such a condition, for example, is where two stations, due to the cancellation of the service or to the moving of the subscribers, have to be disconnected from a standard four-party semi-selective circuit leaving two stations connected to the same side of the circuit. This gives the maximum unbalance produced in this type of apparatus under the various operating conditions.

### RESULTS OF MEASUREMENTS

Prior to the cutting into service of the Bridgeport rectifier station, measurements of the noise on telephone circuits under various conditions were made at some 140 locations in Bridgeport and 50 locations in Stratford. After the installation of the rectifiers, measurements were made only at representative locations.

In Table I is shown the magnitude of noise obtained before and after the Bridgeport rectifier was cut into service in parallel with the rotating machinery in the old generating station. These measurements are representative of the general noise situation on the local telephone circuits.

TABLE I

NOISE UNITS

| Location Bridgeport | *R*-(*T* & *R*) | | *R*-(*T*) | | *R*-bridged | | 2-*R* (*T*) | |
|---|---|---|---|---|---|---|---|---|
| | 1 | 2 | 1 | 2 | 1 | 2 | 1 | 2 |
| A | 20 | 50 | 35 | 75 | 20 | 50 | 35 | 100 |
| B | 10 | 20 | 20 | 35 | 0 | 10 | 20 | 50 |
| C | 20 | 35 | 20 | 50 | 20 | 35 | 35 | 150 |
| D | 35 | 100 | 50 | 125 | 35 | 75 | 75 | 250 |
| E | 20 | 50 | 20 | 75 | 20 | 35 | 35 | 100 |
| F | 20 | 50 | 35 | 75 | 20 | 50 | 50 | 150 |
| Ave. | 20 | 50 | 30 | 70 | 20 | 40 | 40 | 135 |
| Stratford | 1 | 2 | 1 | 2 | 1 | 2 | 1 | 2 |
| A | 20 | 35 | 75 | 100 | 20 | 35 | 75 | 200 |
| B | 20 | 35 | 35 | 50 | 20 | 20 | 35 | 100 |
| C | 20 | 20 | 35 | 35 | 20 | 20 | 35 | 35 |
| Ave. | 20 | 30 | 50 | 60 | 20 | 25 | 50 | 110 |

*R*-(*T* & *R*) = Ringer and condenser connected from each side of circuit to ground.
*R*-(*T*) = Ringer and condenser connected from one side of circuit to ground.
*R*-Bridged = Ringer bridged across circuit, no ground connection.
2-*R* (*T*) = 2 Ringers with their associated condensers connected from one side of circuit to ground.
(1) = Before rectifier was cut in.
(2) = After rectifier was cut in.

The measurements on the private-branch-exchange trunk circuits also showed an increase in the order of 125 per cent, but with the exception of three cases this increase was not sufficient to impair the telephone service seriously. In these three cases it was found practicable to take care of the noise by rearrangements in the telephone plant.

On the day the Bridgeport rectifier was cut into service, complaints were received from a number of telephone subscribers on account of the noise. The private-branch-exchange subscribers were the first to report the interference which in most cases was due to the large increase in the noise obtaining before the central office operator answered. This noise was greatly reduced, however, after the connection was completed. In order to reduce the noise level on some of the other circuits it was necessary to clear up some slight unbalances in the telephone plant which would not have had an appreciable effect with the rotating generating equipment furnishing the power.

There were no appreciable effects noted on the Bridgeport-Stratford interoffice trunk circuits.

When the Stratford rectifier station was put into service there was no appreciable effect noticed on the telephone circuits in Bridgeport except for a small area near the exchange boundary along Stratford Avenue, but in Stratford, especially along Stratford Avenue between the two rectifier stations as shown in the shaded area on Fig. 1, the noise effects were greatly increased and the reactions from the telephone subscribers more serious. The Bridgeport-Stratford interoffice trunk circuits, however, showed no appreciable effects.

After this installation three times as many complaints were received from telephone subscribers as were received when the Bridgeport station was installed. Most of these complaints were from party-line subscribers.

Table II gives a general idea of the noise conditions before and after the Stratford rectifier was installed as well as the results obtained after installing a filter in the railway circuit.

TABLE II

| Location Stratford | *R*-(*T* & *R*) | | | *R*-(*T*) | | | *R*-Bridged | | | 2-*R* (*T*) | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|
| | 1 | 2 | 3 | 1 | 2 | 3 | 1 | 2 | 3 | 1 | 2 | 3 |
| A | 20 | 325 | 150 | 75 | 500 | 300 | 20 | 300 | 125 | 75 | 800 | 450 |
| B | 20 | 100 | 65 | 35 | 200 | 85 | 20 | 100 | 65 | 35 | 275 | 125 |
| C | 20 | 35 | 35 | 35 | 75 | 35 | 20 | 35 | 35 | 20 | 110 | 50 |
| D | 20 | 100 | 75 | 35 | 200 | 100 | 20 | 85 | 75 | 35 | 350 | 200 |

(1) Power from old generating station.
(2) Mercury arc rectifiers at Bridgeport and Stratford.
(3) Same as (2) but with rectifier and filter at Stratford.

## Wave Analysis

A wave analysis of the noise experienced showed 360,- 720,- and 1080-cycle components with the 360 cycle the most prominent. This latter is the fundamental frequency, in this instance, of the ripple in the rectified d-c. voltage wave and is equal to the product of the fundamental frequency of the supply line (60 cycles) and the number of secondary phases of the rectifier (6 phases).

The amount of these harmonic currents flowing over the railway distribution system is a function of the harmonic e. m. f. generated and the load characteristic of the system. Under these conditions, the most practicable means of limiting the flow of these disturbing harmonics on the railway system, and by so doing limiting their interfering effect on the telephone circuits, was to install a filter on the load side of the rectifier. This means of reducing the disturbing harmonics has been used to advantage in other places where the railway current is obtained from mercury arc rectifiers.

## Filter Equipment

The first filter equipment installed in the Stratford substation was only temporary, but similar electrically to the proposed permanent equipment which was in the process of manufacture for both substations.

The equipment consists of a 0.7 millihenry series reactor inserted in the negative return circuit at the station. This reactor acts as a choke to the harmonic currents and of course must be able to carry the entire load current furnished by the station. There are also three resonant shunts connected between the positive and negative sides of the railway circuit on the load side of the reactor in order to by-pass harmonic current at 360, 720, and 1080 cycles, thereby reducing the voltages applied to the line at these frequencies. Each of these resonant shunts has a 2 millihenry air-core coil in series with a bank of condensers. Tuning is accomplished at each frequency by varying the capacity until the harmonic line voltage is a minimum. The capacities obtained for resonance were 105, 28, and 12 $\mu$f., respectively. The condenser banks are built up of 1 $\mu$f. units made to withstand 600 volts direct current indefinitely. See Fig. 3.

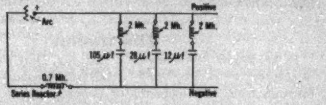

Fig. 3

## Results of Filter Installation

The effect of the filter on the noise levels in the telephone circuits in the Stratford exchange area was quite appreciable and the complaints from the telephone subscribers dropped to only a few cases in the shaded area along Stratford Avenue. The noise measurements obtained are shown in column 3 of Table II. Measurements made with the temporary filter installed in Stratford indicated that a large part of the remaining noise, given under column 3, resulted from the unfiltered rectifier at Bridgeport. It is expected that when a filter is also installed in the Bridgeport substation a further reduction in the noise levels in this particular area will be obtained.

## Conclusion

The magnitude of the interference from a given source, in this case the mercury arc rectifier, depends on the distribution and type of plant of both the street railway system and the telephone system. As shown in Tables I and II, this is clearly indicated by the more serious reactions obtained on the same types of telephone circuits in the Stratford area than in the Bridgeport area. The type of rectifier installed in both areas is the same, but in the Stratford area a larger percentage of the telephone plant is in aerial cable construction with more joint pole line construction with the railway circuits than in the Bridgeport area, where the degree of exposure between aerial telephone and street railway circuits is relatively small.

From the experience obtained with the installation of the six-phase mercury arc rectifiers for the street railway system in Bridgeport and adjacent territory, it can be definitely stated that in general a street railway system energized by mercury arc rectifiers possessing no means of limiting the harmonic components has a greater inductive influence on neighboring communication circuits than when energized by rotating equipment. General experience has shown, however, that by means of properly designed filtering apparatus installed on the d-c. load side of the rectifier, the inductive influence of such a rectifier may be reduced to a level comparable with that of rotating equipment of good wave shape.

---

## Discussion

**P. W. Blye:** In connection with Mr. Daly's paper, it may be of interest to outline briefly interference conditions which have resulted from the operation of mercury arc rectifiers on street railway systems in other locations and to describe the work which has been done jointly by the telephone company and the electrical manufacturers in an effort to provide satisfactory measures for reducing these effects. In all cases of interference which have been investigated so far, the a-c. supply systems have been in underground cable or have not been involved in telephone exposures. The interference has therefore resulted from harmonics in the output side of the rectifier only.

As pointed out in Mr. Daly's paper, the ripple in the output voltage of a mercury arc rectifier consists of a fundamental component and its harmonics, the frequency of the fundamental being equal to the product of the frequency of the supply system and the number of secondary phases. In the case of a six-phase rectifier operating from a 60-cycle supply system, the principal alternating components in the output voltage and current, from the standpoint of inductive coordination, would therefore be a fundamental having a frequency of 360 cycles and its second and third harmonics having frequencies of 720 and 1080 cycles respectively. From measurements made on a number of 600-volt rectifiers in the field, the average magnitudes of these three components have been found to be as follows:

| | |
|---|---|
| 360 cycles | 32 volts |
| 720 cycles | 8 volts |
| 1080 cycles | 3.5 volts |

The a-c. components impressed on the trolley and feeder system by a rectifier are, of course, a function of the above voltages and the impedance of the system. The impedances of the systems investigated so far have been found to be inductive reactances which tend to suppress the higher frequency current components. In a representative location in which severe inductive interference was experienced, the most important a-c. components in the trolley and feeder system were found to be as follows:

| | |
|---|---|
| 360 | 17.5 amperes |
| 720 | 2.0 amperes |
| 1080 | 0.5 ampere |

Experience so far has been chiefly with 6-phase rectifiers. A limited amount of experience with 12-phase rectifiers has indicated that while the inductive effects are less than with 6-phase devices there is an inductive coordination problem here also.

In single substation areas the individual stub-end feeders offer a relatively high impedance to the alternating currents generated by rectifiers. In the case of tie feeders connecting rectifier substations with other stations in which rectifiers or rotating equipment are in operation, however, this terminal apparatus provides a low impedance path for the alternating currents and relatively large currents may be expected in such feeders. A somewhat similar situation exists in the case of single substation areas where main feeder routes are involved. The most serious cases of interference may therefore be expected from tie feeders of this character.

Coordination between exposed telephone circuits and street railway trolley and feeder systems such as these which, of course, employ a ground return, is difficult owing to the fact that power system transpositions are impossible.

During the past year, interference has been experienced from a number of rectifier installations in this country and in Canada. While practically all types of telephone service have been affected, the most serious effects have been noted in the case of interoffice trunk circuits, party-line subscribers' circuits, and private-branch exchange systems.

The severity of the interference, of course, varies considerably with the separation of the power and telephone systems. The most severe effects have been noted on telephone circuits carried in aerial cables on the same poles with the trolley system feeders. Serious effects have, however, been noted in long exposures on similar aerial cables located several hundred feet from the trolley system. In a majority of cases the noise has been found to be due to electromagnetic effects resulting from a-c. components in the feeder system.

In one of the most severe cases of interference, noise was measured on party-line circuits in the affected area of the order of 1000 to 2000 units. On interoffice trunk circuits in this area, noise of from 1500 to 2000 units was observed. A number of P.B.X.'s was also seriously affected and while conditions in these cases were improved somewhat by measures taken in the telephone plant, it was not possible to reduce the noise to a satisfactory level by this means. Several other similar cases of severe interference have been experienced as well as a number of cases of a less acute nature such as those in Bridgeport and Stratford, covered in Mr. Daly's paper.

During the past year cooperative studies have been carried on by the manufacturers and the telephone company on methods of improving the wave-shape of rectifiers. This work has indicated that the most effective arrangement is a filter employing a series reactor and a number of shunt branches tuned to the frequencies of the various alternating components to be suppressed. In such a filter the series reactor must carry the full d-c. output of the rectifier. The shunt condensers must withstand the maximum voltage to be expected on the system. These condensers and the shunt coils must carry continuously alternating voltages generated in the rectifier divided by the reactance of the series reactor.

In one of the cases in which severe interference was experienced the filter arrangement used was the same as the temporary installation at Stratford described by Mr. Daly. This filter proved entirely satisfactory as a means of reducing the interference, the important alternating voltage and current components and, therefore, the induced noise, being reduced in ratios of the order of 10:1. Installations of a generally similar type have been made in other locations, and in each case the telephone circuit noise has been reduced to a level comparable to that experienced with the rotating equipment formerly used.

The permanent filters for the Connecticut rectifiers have only recently been installed and complete measurements of their effectiveness have not yet been made. Preliminary measurements in the Stratford Area indicate, however, a reduction in the noise of approximately 8:1.

The results of the cooperative work so far have indicated that satisfactory coordination can be effected between telephone circuits and the d-c. street railway circuits when the latter are supplied either by rotating equipment or by rectifiers equipped with suitable filters.

**R. G. McCurdy:** Mr. Daly's paper on the effect of mercury arc rectifiers on communication circuits treats the matter of coordination between the street-railway feeders and trolley system, and local telephone circuits. He has shown that it is practicable to coordinate such street railway and telephone systems when mercury arc rectifiers are used as the converting equipment and provided suitable filters are employed with the rectifiers. The matter of the effect of the mercury arc rectifiers on coordination with a-c. supply lines has not been covered.

Inductive coordination difficulties so far experienced by the Bell Telephone Companies with power circuits employing mercury arc rectifiers have been confined to the d-c. side. The a-c. feeders to the mercury arc rectifiers have either been in cable or else in relatively short overhead feeders not involved in any extensive exposures with telephone circuits.

In connection with various tests which have been made on rectifier installations in cooperation with the manufacturers and operating companies, considerable data have been gathered on the effect of the rectifiers on the wave shape of the a-c. system from which it is supplied. This has indicated that the six-phase mercury arc rectifiers take an alternating current having a telephone interference factor, in the case of 60-cycle systems, of from 300 to 500. There are present all the odd non-triple harmonics, being the harmonics immediately below and immediately above the even harmonics appearing on the d-c. side. The experience with 12-phase rectifiers has been less extensive but it is expected that the harmonics and the telephone interference factor will be lower than with 6-phase rectifiers.

The wave-shape distortion introduced into the a-c. voltage wave will, of course, depend upon the impedance of the a-c. system from which the rectifier is supplied. In a large system with comparatively short feeders, the distortion in the voltage wave will be comparatively small. With comparatively long feeders or a system of small size, considerable voltage distortion may be experienced.

Where overhead lines supplying mercury arc rectifier loads are involved in exposures with open-wire telephone lines, the difficulties of inductive coordination will be greatly increased over that experienced with the usual type of load. The degree of difficulty will increase with the increase in voltage and current telephone interference factors caused by the use of the rectifier. This problem is much more likely to be met with in cases of interurban electrifications or electrifications of main line railroads involving a-c. transmission over considerable distances than in street railway installations where the a-c. feeders will more often be in cable.

**J. W. Milnor:** It may be of interest to mention the experience of the Western Union Telegraph Company in connection with interference from installations of mercury arc rectifiers.

These remarks will be confined solely to inductive interference with telephone-circuit operation. We have not yet found any serious interference with the types of telegraph circuit now generally employed in handling the company's business. Our general experience indicates that interference from the trolley (d-c.) side of a rectifier installation is severe to telephone circuits if filters are not employed. Such interference, however, is mitigated considerably by the employment of the type of filter which Mr. Daly described.

Mr. Daly has confined himelf to the discussion of interference from the trolley (d-c.) side, and it is here I think that one's impression might be somewhat misled, if some mention were not made here concerning the other effects. The telegraph company has been concerned with one case where its line is paralleled by both the a-c. and d-c. sides of a rectifier system. The 6th, 12th, and 18th harmonics were found to be reduced by the filters, but the interference remaining was found to be severe at harmonics of the frequency of 5, 7, 11, 13, 17, and 19 times the fundamental (60 cycles). You will note that these frequencies are one harmonic removed above and below the 6th, 12th, and 18th which are characteristic of rectifier operation from a 60-cycle source. I regret that our investigations have not proceeded far enough so that we can present a more detailed discussion of this odd-harmonic induction, possibly to be attributed to the a-c. side of the rectifier system.

Our experience indicates that it is most desirable that further investigation be made so that we may have a better understanding of the matter of proper inductive coordination for rectifier installations. It is to be hoped that manufacturing companies and utilities contemplating the use of rectifiers where communication circuit parallelisms are involved, will give considerable thought to this matter prior to making a choice as to the type of equipment to be used in providing direct current for propulsion circuits.

**O. K. Marti:** In regard to Mr. McCurdy's discussion I should like to mention that interference due to an a-c. line supplying rectifiers is probably to be feared only if the entire load consists of rectifiers. In case the a-c. supply line also furnished power to other apparatus, such as motors, lights, etc., the rectifier load will not produce a distortion of the alternating current to any considerable degree. Since in almost every case some other load is connected to the line supplying a rectifier, this problem does not seem to be so serious. Besides, in cities and larger towns all the supply lines are brought into the substations in cables, which again will eliminate the possibility of interference with communication circuits. Due to the fact that the rectifier load is always a three-phase balanced load, the third harmonic and its multiples are eliminated from the line current by the transformer connections used. There is no residual line current and therefore very little possibility of interference. Further, it might be possible to improve conditions, where interference does exist, by alternately connecting a rectifier in delta and another one in star on the primary side, as this method of connection might filter out some of the harmonics.

**W. B. Hall:** I should like to show an oscillogram, taken at the Congress St. Substation, of the actual waves whose effects the previous speakers have been analyzing.

At very light load, the direct voltage will consist of successive peaks of the six-phase sine waves, as each anode carries the load alone for one-sixth of a cycle. The variation in voltage is from 0.866 to 1.000 or 13.3 per cent.

With heavy load (as shown in the top curve of the oscillogram, Fig. 1), the reactance of the six-phase transformer causes the anode which is carrying the load to continue to supply current, and causes the incoming anode to pick up the current gradually, so there is a period of overlapping during which two anodes are sharing the load. During this period, the direct voltage is as much below the incoming anode's sine wave as it is above the outgoing anode's sine wave, since the outgoing anode is dropping its load at the same rate that the incoming anode is picking it up, and therefore $L \frac{d i}{d t}$ for one equals $L \frac{d i}{d t}$ for the other. Hence the direct voltage follows a line exactly halfway between the two sine waves, as shown in Fig. 2, until the current in the outgoing anode has entirely ceased, when the direct voltage suddenly jumps to the sine wave of the incoming anode. The variation here is more than the 13.3 per cent, the amount depending upon the length of the period of overlap which depends upon the load.

But this is the wave of voltage variation, which could cause interference only by capacity coupling. The effect of capacity coupling at 600 volts is negligible. Most of the interference is by inductive coupling with the direct *current*. This current goes mainly to series motors which are highly inductive and draw a current wave much smoother than the voltage wave (see feeder current in the oscillogram). These oscillograms are all taken without the d-c. filter in service.

FIG. 1

This direct current is supplied successively by each anode in turn. Hence each anode supplies a direct current for 60 deg., then none. The anode current then is one rectangular block 60 deg. long for each cycle (see oscillogram).

The transformer primary current is the same as the anode current. But since the primaries are delta-connected, the line current has two successive anode current blocks in it. Hence the a-c. line current consists of a rectangular wave for 120 deg., then zero for 60 deg. and so on. The curve marked a-c. primary current shows this, superimposed upon the transformer exciting current. These changes in line current are much more severe than the changes in the d-c. wave, and they are not remedied by inductance in the load or by d-c. filters. There would be much more inductive interference from the a-c. line than from the d-c. output, with equivalent exposure. Of course, the exposure of telephone lines to power lines is usually much less than to d-c. feeders and trolley wires.

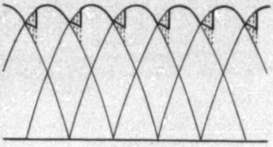

FIG. 2

The oscillogram (a-c. volts) shows the effect of this current wave on a-c. line voltage.

**J. J. Smith:** Mr. Daly points out in his conclusion that the interference from a given source depends on the distribution and type of plant of both the street-railway system and telephone system. The rectifier by nature of the mechanism through which it converts alternating current into direct current gives rise to harmonics in the d-c. voltage wave. If it were possible to obtain a rectifier which did not produce harmonics there would be no problem of telephone interference. On the other hand, even though harmonics are present in the power system, there would again be no problem of this type of telephone interference if the telephone lines were perfectly balanced. The real problem of interference is therefore to reduce the harmonics on the power system and the unbalances on the telephone system as far as is economically practicable.

On making a comparison in Table I under *R*-(*T* & *R*) 2 and 2-*R* (*T*) 1 it will be noted that the average noise units in each case are approximately the same although one set of measurements was made when the rectifiers were operating and the other set before the rectifiers were cut in. It will also be noted that with the rectifiers operating the average noise units in the telephone lines varied 3 to 1 due to the different degrees of balance in the telephone circuit.

While in theory any desired reduction in the 360-, 720-, and 1080-cycle components may be obtained by the use of reactors and resonant shunts, the addition of such equipment adds to the costs of the rectifier and the d-c. reactor introduces losses into the circuit, lowering the efficiency. It is, therefore, undesirable to make this apparatus any greater than is absolutely necessary.

Thus it would appear that the problem of interference from mercury arc rectifiers is a mutual one between the telephone engineers and the power engineers. The telephone engineers can reduce the noise considerably if they find means to take care of the unbalanced arrangement of selective ringers referred to in the paper, under 2-*R* (*T*) for instance, while the power engineers can assist in the reduction by the addition of filtering equipment.

It would be very interesting if Mr. Daly would amplify his paper slightly to give some idea of the exposures of the telephone lines to the trolley lines. I assume that the difference in noise units at different points is due to the different exposures of the telephone lines. In order to bring the data into a form in which they might be used for comparison with other rectifier installations, it would also be necessary to give the magnitude of the harmonics in both the voltage and current in the d-c. wave form of the rectifier.

In Fig. 3 in the paper the capacities and inductances given do not tune for the 6th, 12th, and 18th harmonics of 60 cycles. I find on checking up that the points at which they tune are 347, 675, and 1030 cycles. This is probably due to the fact that the coils are only approximately 2 millihenries. It might be well, however, to state this as it might lead to some confusion in the minds of persons reading the paper.

**C. J. Daly:** I feel that Mr. Marti is unduly optimistic as to the effect of reducing the harmonics by means of other loads connected to the a-c. line supplying a rectifier. It would be necessary that the impedance of such loads be small as compared to the impedance of the transmission line or feeder in order to produce any large reduction in the magnitude of the harmonic components transmitted over the line or feeder. It is also essential that the telephone exposure should not be located between the rectifier and these low-impedance loads.

In reference to the discussion by Mr. Hall, experience has shown that the induction from the d-c. side arises principally from the current harmonics. While these currents are small compared to the load current, as indicated by the oscillogram shown by Mr. Hall, the inductive effects are proportional to the magnitude of the harmonic components and not proportional to their values relative to the d-c. load current. As will be noted from the various values given in Mr. Blye's discussion, values of 360 cycles of the order of about 18 amperes have been noted when filters were not employed in the d-c. side.

I am somewhat uncertain as to the meaning of the term "equivalent exposure" used in Mr. Hall's discussion. It is evident, however, that if the a-c. feeders consisted of one wire with rail return as in the case of the d-c. side, the interference from the a-c. side would be much more severe.

Mr. Smith's assumption that the difference in the noise values experienced on the telephone circuits was due to the difference in the degree of exposure is correct. For example, in the case of the telephone circuit to the *A* location on which 800 noise units were experienced, the exposure was much more severe than in the case of the telephone circuit to the *C* location where 110 noise units were obtained. The former circuit is in underground construction which parallels the railway tracks for about one-quarter mile and then extends in aerial cable for a distance of about one-half mile on the same pole line with both positive and negative railway feeders. The latter telephone circuit is approximately one-half mile in length, entirely in underground cable construction with an exposure of about one-quarter of a mile to the railway tracks.

In reference to the resonance points of the capacities and inductances, it may be pointed out that the coils are only approximately 2 millihenries and the capacitance values given are in terms of the nominal values of the condenser units. The actual capacitance may vary from these nominal values in the order of one per cent. As explained in the paper the branches were adjusted to be in resonance at the actual frequencies of the various harmonics to be reduced.

# Rocky River Hydroelectric Development
## Of The Connecticut Light and Power Company

BY E. J. AMBERG[1]

Associate, A. I. E. E.

***Synopsis.**—This paper describes the Rocky River hydroelectric development of the Connecticut Light and Power Company, near New Milford, Connecticut, which is a storage development for regulating the Housatonic River below New Milford.*

*There are no sites on the main river suitable for a large storage reservoir. It was therefore necessary to select a site on a tributary, the Rocky River. The run-off from the natural drainage area of the reservoir basin furnishes only a part of the water required to fill the reservoir, making it necessary to pump the balance from the Housatonic River against a maximum head of 240 ft. This is the first large application of pumped storage in the United States which accounts for the general interest shown in the Rocky River development.*

*The first part of the paper deals with the factors which have to be considered in determining the economic possibilities of such a development. The second part of the paper is a description of the main features of the development itself.*

* * * * *

THE Rocky River hydroelectric development of the Connecticut Light and Power Company has created considerable interest among technical as well as non-technical men, as a project for regulating the flow of the Housatonic River below New Milford, Connecticut. Briefly, the development consists of a storage reservoir created on Rocky River, a tributary of the Housatonic, with a power and pumping plant on the Housatonic River; the power and pumping plant being connected by a single penstock with the reservoir.

Fig. 1 shows the location of the Rocky River development in relation to the system of the Connecticut Light and Power Company and its associated companies. Fig. 2 shows, on an enlarged scale, the vicinity of the Rocky River development. The Rocky River basin is located north of Danbury and west of the Housatonic River, and the site of the development is approximately 1½ mi. by state highway from the nearest railroad station at New Milford. The basin has a drainage area of approximately 40 sq. mi., eight and one-third of which are covered by the storage lake. The branches of the Rocky River heading near Danbury flow north to meet the branch of the river which heads near Sherman and flows in a southerly direction. From the junction of these branches, the river flows north through marshy flats which form the bottom of the reservoir, to a point 2½ mi. from the junction of the Rocky River with the Housatonic, wherein Rocky River falls about 200 ft. over a rocky bed. The shores of the reservoir are for the most part steep and rocky, rising to elevations of from 500 to 1000 ft. They are well covered with second growth timber together with some virgin timber in the more inaccessible locations.

The unusual features of this development lies in the fact that the drainage area of the reservoir basin will supply only about 1.5 billion cu. ft. of water in an average year while the useful capacity of the reservoir is 5.9 billion cu. ft. All water above the natural run-off required to fill the reservoir must be pumped from the Housatonic River against a head varying from 200 to 230 ft. While considerable excess hydro energy will be available for pumping, the studies and investigations for this development are all based on using secondary steam energy for pumping, to be supplied from the

Devon steam station of the Connecticut Light and Power Company.

The Rocky River reservoir may be likened to a large storage battery. Charging the battery is accomplished by secondary steam energy from Devon driving two 8100-hp. centrifugal pumps, delivering water to the reservoir. The battery is discharged by means of the 30,000-kv-a. generating unit delivering primary hydro energy.

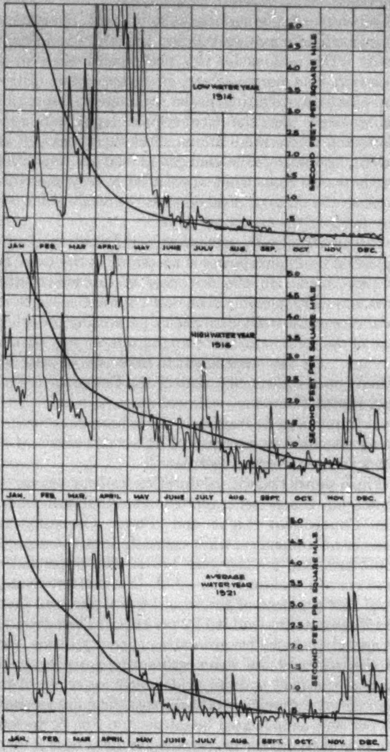

FIG. 3—HYDROGRAPHS OF THE HOUSATONIC RIVER

Showing hydrographs and superimposed flow duration curves for a low water year, a high water year, and an average water year

The efficiency of this storage battery for changing secondary steam energy into primary hydro energy is 61 per cent; this includes all losses from the 66,000-volt bus at the Devon Steam Station through the pumping units into the reservoir and back through the generating unit to the 66,000-volt Rocky River bus. In other words, for every 100 kw-hr. supplied by the Devon Steam Station in filling the reservoir, 61 kw-hr. are delivered by the Rocky River generating unit, when the water is drawn out again. We must not, however, overlook the fact that below the Rocky River plant there is an additional total average head of 191 ft. available, of which 71 ft. is efficiently developed at Stevenson. If the head at Stevenson is added, then for every 100 kw-hr. of steam energy, 79 kw-hr. of hydro energy are returned. If the total head from Rocky River to tide-water is added, 111 kw-hr. of hydro-energy could be obtained from every 100 kw-hr. of steam energy used in pumping.

Before going into a more detailed description of the Rocky River project, it is desirable to review, briefly, two factors which are essential to understand the basis upon which Rocky River has been developed. These two factors are: the hydrology of the Housatonic River, and the general character of the system load curves of the Connecticut Light and Power Company.

It is generally known that the rivers in the eastern part of the country have a very irregular flow, unless some natural or artificial means exists for regulation. The Housatonic River, with which we are concerned, had no means of regulation; the stream flow shows very wide variations, as can be seen from Fig. 3, showing hydrographs and duration flow curves for a typical wet, average, and dry year. From the hydrographs, it is quite evident that the only period of the year when any reliance can be placed on the river flow is in the Spring-time. The rest of the year the flow is quite irregular. While frequently a somewhat larger flow may be ex-

1. Generated at Stevenson on water discharged from Rocky River

pected in the Fall, there is no certainty of it, as shown for the dry year, where the low water condition continued right to the end of the year. With the river plants at Stevenson and Bulls Bridge operated in conjunction with the Rocky River storage plant the 24 hr. firm power of the hydro system is 11,000 kw. Fig. 4 shows the unregulated power duration curves for a typical dry, wet, and average year, limited by the installed capacities of the Stevenson and Bulls Bridge stations which together total 26,000 kw. The regulated 24 hr. firm power of 11,000 kw. obtained by the addition of Rocky River is also shown. The respective areas between the 11,000 kw. regulated firm power and the power duration curves represent the energy which has to be furnished from storage. The amount required in each year varies considerably, being 9,500,000 kw-hr. in the wet year and 39,900,000 kw-hr. in the dry year. Of these amounts, 78 per cent is produced by the Rocky River station and the balance at Stevenson, generated from the water released from Rocky River station.

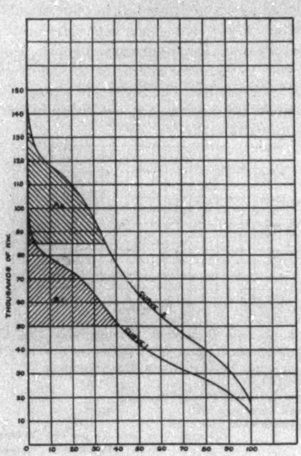

FIG. 5—LOAD DURATION CURVES

| | Curve No. 1 | Curve No. 2 |
|---|---|---|
| Max. kw-hr | 100,000 | 150,000 |
| Load factor | 47.3% | 47.3% |
| Hydro kw | 50,000 | 65,000 |
| Increase | | 15,000 |
| Hydro load factor | 17.2% | 13.2% |

Hydro area $A_1$ = hydro area $A_2$

By applying the 24-hr. firm power of 11,000 kw. to the upper half of the load curve, as shown in Fig. 5, curve 1, the total installed hydro capacity of 50,000 kw. can be used as firm capacity. Before regulation by Rocky River, the combined firm capacity of the Stevenson and Bulls Bridge stations was only 10,000 kw. although the installed capacity was 26,000 kw. Therefore, by installing a 24,000-kw. generating unit in the Rocky River station and by regulating the river the firm hydro capacity has been increased by 40,000 kw.

To obtain maximum benefit from such a storage development, it is necessary to apply it to that part of the load requiring the smallest number of kilowatt hours. This brings us to the second factor, the load curves.

When plotting system loads in the form of an annual duration load curve we will find that there is a decided peak. The reasons for this pronounced peak on the duration load curves, vary; in metropolitan districts the short-time lighting peaks are largely responsible; on systems like the Connecticut Light and Power Company where there are no short time peaks, of any extent, the seasonable changes in load are responsible. In the latter case, what appears as a very short-time peak on the duration load curve is the result of the 9-hr. day loads of the maximum days.

It can readily be seen that a different method of applying the hydro power is necessary in the two cases of peak load. In the first case of the metropolitan area, a weekly, possibly even daily, storage capacity will take care of the individual peaks, permitting the utilization of the river for actual demand without any seasonal storage. On the other hand, to take care of peak conditions on a system like that of the Connecticut Light and Power Company, seasonal storage in addition to weekly pondage is required. This seasonal storage is being provided in our case by the construction of the Rocky River storage reservoir.

Fig. 5 shows two annual duration load curves; curve 1 represents the present approximate combined load of the Connecticut Light and Power Company and associated companies, while curve 2 shows the expected combined load for the year 1931. The upper half of load curve 1 and load curve 2 for that matter, contains only 18.2 per cent of the total kw-hr.; the load factor of this part of the load is 17.2 per cent. The advantage of applying the hydro generating capacity to the peak of the load and the steam generating capacity to the base of the load is quite evident from a study of this load curve. Assuming that the total load has increased 50 per cent as indicated by curve 2 on Fig. 5, the same number of hydro kw-hr. represented by area A 2 would permit a firm hydro capacity of 65,000 kw. as against 50,000 kw. firm capacity of curve 1; or 15,000 kw. firm capacity could be installed without increasing the storage facilities. Additional capacity can often be installed at a low cost per kilowatt in existing plants, thus lowering the average unit cost per kilowatt of hydro capacity.

Such a storage development as Rocky River has therefore some inherent values which can be increasingly realized as the load increases.

Aside from the features discussed above, hydro plants have another great advantage in that they provide standby capacity which can be made available in a fraction of the time required at a steam station, because to get up steam and warm up a turbine requires time unless boilers are kept in service and excess turbine capacity is kept on the line to take care of sudden load demands.

With the means of regulating the stream flow below Rocky River, it will be possible to develop the full head on this section of the river, which will then produce a total 24 hr. firm power of approximately 23,000 kw.

The hydro capacity will again be applied to the upper half of the load curve, which from curve 1 on Fig. 5 shows a load factor of 17.2 per cent. In order to take care of possible changes in the load curve we will make an arbitrary increase in the load factor of one-third, which will change this load factor to 23 per cent. With a 23 per cent load factor and a 24 hr. firm power of 23,000 kw. it will be possible to increase the total installed hydro capacity to 100,000 kw. by developing the full head of the river between tide-water and Rocky River.

The second 24,000-kw. unit at Rocky River is in addition to the 100,000-kw. capacity above referred to; its main function will be to act as a spare unit, which can be made instantly available. The second unit can be installed at a low unit cost including the raising of the reservoir level which will add approximately one billion cubic feet to the useful storage capacity.

From the above can be seen that the Rocky River development has a considerable increased future value, by making it possible to develop the full head below Rocky River as the load of the system of the Connecticut Light and Power Company and associated companies increases. Without Rocky River further economic development of the river would have been impossible.

In concluding the first part of this paper an account of water utilization at Rocky River and Stevenson stations for a typical average year seems in order.

As stated before with a full reservoir the water level will be at elevation 430 ft. The normal allowable draw-down is 30 ft., or to water level elevation at 400 ft. In this 30 ft. of draw-down, 5.9 billion cubic feet of water are taken from the reservoir. This amount of water, in going through the Rocky River generator will produce 24,200,000 kw-hr.

From the power duration curve for an average year in Fig. 4, it will be seen that 22,300,000 kw-hr. must be generated by water from Rocky River to maintain the 24 hr. firm power of 11,000 kw. Of the total of 22,300,000 kw-hr. the Rocky River station will furnish 17,400,000 kw-hr. while the remaining 4,900,000 kw-hr. are generated at the Stevenson station by the water discharged from Rocky River station. The amount of water that must be taken from the reservoir in order to produce 17,400,000 kw-hr. at Rocky River station is approximately 4030 billion cu. ft., based on an average figure of 15.55 kw. per sec. ft.

The water used for refilling the reservoir falls into two classes with two subdivisions in each class.

1. Run-off water from the Rocky River drainage area; this is subdivided into

   a. Water held back at a time when it would have spilled over the Stevenson dam.

   b. Water held back at a time when it could have been used at the Stevenson station.

2. Water taken from the Housatonic River and pumped into the reservoir, subdivided into

   a. Water taken from the Housatonic River at a time when this water would have spilled over the dam at Stevenson.

   b. Water taken from the river at a time when this water could have been used at the Stevenson station.

The following is a brief summary of the amount of water obtained from each subdivision for an average year.

1. The run-off from the Rocky River drainage area in an average year based on a net area of 35 sq. mi. is 1.6 billion cu. ft.

   a. The daily discharge records for the average year show that there are 58 days of the year when the flow of the river equals or exceeds 2.86 cu. ft. per sec. per sq. mi., the flow necessary to produce 24 hr. full-load at Stevenson. The run-off during the 58 days amounts to 0.84 billion cu. ft. This amount of water, when finally released from the reservoir will utilize the additional head at Rocky River as well as at Stevenson.

   b. The difference, or $1.6-0.84 = 0.76$ billion cu. ft., is Rocky River run-off that is caught in the reservoir at a time when the river flow was less than 2.86 cu. ft. per sec. per sq. mi. This amount of water, when finally released, will utilize the additional head of the Rocky River station only.

2. The total amount of water to be pumped in an average year is $4.03-1.6 = 2.43$ billion cu. ft. The possible number of pump hours per week with two pumping units available is 336 hr. Load conditions, however, will normally limit the actual pump hours per week to 200 hr. which corresponds to an average pumping rate of 298 cu. ft. per sec. as against the maximum possible rate of 500 cu. ft. per sec., which is the capacity of the two pumps.

   a. The daily discharge records for the average year show that there are 58 days of the year when the flow of the river equals or exceeds 2.86 cu. ft. per sec. per sq. mi., the flow necessary to produce 24 hr. full-load at Stevenson, and 45 days when the river flow equals or exceeds 3.16 cu. ft. per sec. per sq. mi., the flow necessary to produce 24 hr. full-load at Stevenson after an average of 298 cu. ft. of water per sec. has been taken from the river at the Rocky River station. The amount of water pumped during this period is 1.32 billion cu. ft. This water when released from the reservoir will utilize the additional head at the Rocky River and Stevenson stations.

   b. To completely fill the reservoir, an additional amount of $2.430-1.325 = 1.105$ billion cu. ft. of water must be pumped at a time when the river flow is less than 2.86 cu. ft. per sec. per sq. mi. This water when released from the reservoir will utilize the additional head of the Rocky River station only.

TABULATION SHOWING SUMMARY OF WATER USED FOR FILLING THE ROCKY RIVER RESERVOIR IN AN AVERAGE YEAR

| Classification | Water | Amount of water billions of cu. ft. | Will use "additional" head of Rocky River station | Will use "additional" head of Stevenson station |
|---|---|---|---|---|
| 1 (a) | Run-off exceeding full-load flow | 0.840 | Yes | Yes |
| 1 (b) | Run-off below full-load flow | 0.760 | Yes | No |
| 2 (a) | Pumped water exceeding full-load flow | 1.325 | Yes | Yes |
| 2 (b) | Pumped water below full-load flow | 1.105 | Yes | No |
|  | Total | 4.030 |  |  |

## DESCRIPTION OF THE ROCKY RIVER DEVELOPMENT

*Reservoir and Dams.* The storage reservoir or lake is about 10 mi. long and 1¾ mi. across at the widest part. It has a surface area of 8⅛ sq. mi. and a shore line of approximately 60 mi. The creation of a lake of this size made it necessary to abandon and relocate highways and homes. Approximately 31 mi. of highway were abandoned and 9¼ mi. of new and relocated highway were built. Six cemeteries were relocated. Outside of several summer colonies located around the four ponds included in the basin, only 35 families with permanent residences were affected by the construction of this reservoir, which is an unusually small number considering the area covered. The bottom of the reservoir was for the most part swampy ground, and 4500 acres were covered with woods.

The main dam is located across Rocky River at a point about one mi. above its junction with the Housatonic River. It is an earth filled dam with a core wall. The lower part of this core wall consists of a two ft. concrete section which extends on the average ten feet above and an average of five feet below the ground surface. On top of this concrete section was placed a six in. Wakefield core wall (timber) reaching up to elevation 435 ft. On the west end, the concrete core wall was located in solid rock. This rock, however, dropped off rapidly below the surface at the location of the old river bed; from this point the core wall continued in earth. Fig. 6 showing a cross-section and plan of the dam gives a better idea of its construction than a lengthy detail description.

To take care of Rocky River during the construction of this dam a concrete conduit approximately 4 by 5 ft. was located near the original river bed. A small auxiliary earth dam with wooden sheet piling was erected across the river bed near the entrance to this concrete conduit, to create a small pond from which water could be pumped for the sluicing operation. The intake to this concrete conduit was equipped with a heavy wooden gate hinged at the top, used for closing off the flow through the conduit after completion of the dam. The material for the dam was obtained from the canal excavation, and was placed in the dam by sluicing. The relative elevations were such that only a very small quantity could be sluiced directly. So practically all of the material was excavated with drag lines and placed into large piles. It was then sluiced from these piles down into the dam. However, after the dam had reached a certain height, the slope in the sluicing line became insufficient; this was partly due too, to the increased distance of the drag line from the dam. When this point was reached the material was sluiced to a pumping plant located at elevation 375 ft. Before being delivered to the pumps, the material was passed through a revolving screen which eliminated all stone over 6 in. in diameter.

On the dam itself, a gasoline driven drag line was utilized to throw up small dikes on each edge to hold the water within the dam and give the sluiced material a chance to settle. Near the center of the dam was a concrete chimney with openings which acted as overflows for the sluicing water. The chimney connected at the bottom with the concrete conduit under the dam. As the dam came up the openings were closed up. The dike along the canal was constructed in a similar manner, as it constitutes practically an extension of the main dam.

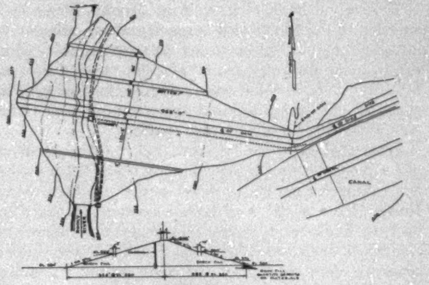

FIG. 6—PLAN AND CROSS-SECTION OF THE MAIN EARTH DAM

To take care of some low points in the rim of the basin five smaller dams were necessary. Two of the dams are near Danbury. Both are earth dams of the same general design as the main dam. The material for these dams had to be hauled in as there was no water available for pumping the material from the borrow pits. It was wetted down and rolled. The other three dams are located near Lanesville. The north and south Lanesville dams are constructed of concrete. The so-called Lanesville Gap was closed by an earth dam similar in design to the main dam. Seamy rock at the west end of this dam presented considerable difficulties in obtaining a tight job. The concrete section on which the 6 in. Wakefield core wall rested was considerably enlarged; in addition a considerable number of grout holes was put in the rock. The material was placed in this dam by sluicing.

The crest of the main dam and the Danbury dikes is at elevation 442 ft., or 12 ft. above the present normal maximum reservoir level at elevation 430 ft.

The crest of the dike at the Lanesville Gap is at elevation 440 ft. or 2 ft. lower than the crest of the main dam. This dike is located in a cove which practically eliminates all wave action, which accounts for the 2 ft. lower crest.

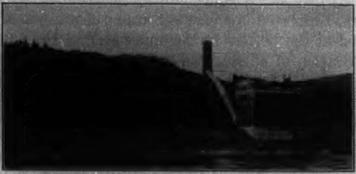

Fig. 6a—General View of Power House Penstock and Substation

The present crest of the concrete section of the South Lanesville dam is at elevation 432 ft. and of the North Lanesville dam at elevation 431 ft. Each of these concrete dams is so designed that the concrete sections can later be raised four feet at a nominal cost. This construction would be done in order to raise the level in the reservoir from 430 ft. to 435 ft., which would add approximately one billion cubic feet to the reservoir. The future maximum water level in the reservoir is 440 ft., or an increase of 10 ft. over the present level. However, to raise the level to 440 ft. would require considerable additional construction work.

*Intake.* The canal leading from the reservoir to the intake was excavated for about 3300 ft. along the east bank of the valley. Terminating the dike in the side hill permitted the construction of a circular intake tower in the canal with only a short length of concrete conduit extending through the dike. Six equal intake openings are located in the half of the tower facing the canal. Each opening is protected by vertical trash racks provided with a compressed air rack raking device, and each opening can be closed by steel stop logs operated by means of manually operated hoists. A self-closing sliding Broome gate is located at the entrance to the concrete conduit in the tower and operated by electric hoist. Ample air-vents to the penstock are provided in the intake structure back of the gate. Necessary by-pass pipe connections are provided to fill the penstock from the intake with the Broome gate closed, and for filling the intake from the canal with the steel stop logs in position.

*Penstock.* The concrete conduit, having an inside diameter of 16 ft., extends only a short distance from the intake tower to the wood stave pipe line. This wood pipe line has an inside diameter of 15 ft. and extends for approximately 1007 ft. along the hillside. The average gradient is 0.5 ft. in 100 ft. The intake tower and wood pipe line are of sufficient capacity for the installation in the future of a second generating unit. The wood pipe line joins a steel penstock *Y*-connection; one of the two branches is blanked off ready for a second penstock for the future unit, while the other extends a short distance to a Johnson differential surge tank. Freezing of the water in this surge tank is prevented by agitation with compressed air. The compressed air pipe line follows the penstock from the power house, branching off at the surge tank, and on up to the intake for the air raking device, as previously mentioned. From the surge tank the penstock drops down the hillside to the power house (Fig. 6a). The inside diameter varies from 13 ft. to 11 ft. just outside the power house, where there is another *Y*-connection, one branch for the generating unit and the other for the two pumping units. Each branch has a Venturi section for measurement of flows. Fig. 7 shows the general layout of the penstock.

*Power Station Building.* Like most modern power house construction, the substructure of Rocky River plant is built exclusively of concrete, with a small amount of steel work to support the lighter floors. The foundation rests on bedrock, which was so close to the elevation desired, that little rock had to be taken out or extra concrete put in. The concrete barrel type of construction was used, wherein the entire weight of generator, shaft, runner, and hydraulic thrust is carried through a concrete barrel and the turbine speed ring, to the foundations. The south end of the building, referred to as the switch bay, is supported on reinforced concrete columns. All the surface of the concrete substructure was coated with a water-proofing compound.

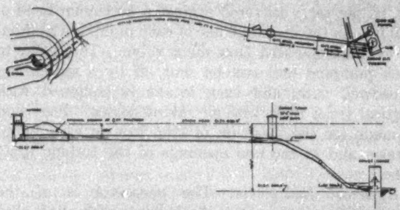

Fig. 7—Plan and Profile of the Pipe Line and Penstock

The power house superstructure is of structural steel framework and brick. Precast gypsum slabs provide the foundation for an asphalt built-up roof. All exterior trim of the building is of precast cement blocks.

There are four floors in the switch bay with a control cable terminal room below the first floor. The first floor is the control room with the switchboard. The second floor contains the 13,200-volt pump motor bus and switching, and the third and fourth floors are used for the 4600-volt distribution bus and storage battery room.

*Hydraulic Equipment.* The hydraulic equipment of the power station consists of one 33,300-hp. vertical shaft turbine and two 8100-hp. vertical shaft centrifugal pumps. A noteworthy feature of the turbine is the cyclinder gate which replaces the more conventional Butterfly or Johnson valves for directly shutting off the flow of water to the turbine. This cylinder gate is built in the turbine in the annular chamber between the pit liner and the speed-ring. It is operated from a valve on the generator floor which controls the admission of water under penstock pressure to the annular chambers above the valve. Positive mechanical locking devices hold the valve in either a full, open, or closed position.

The turbine is equipped with a 110,000 ft. lb. actuator governor located on the generator floor, arranged to operate the turbine gates by two cylinders in the turbine pit. Oil is supplied to the governor system at 200 lb. per sq. in. by an a-c. motor driven screw pump. The governor of this unit consists of a centrifugal speed element driven by a synchronous motor.

The centrifugal pumps, as far as I could find out, are the largest in the United States. The pump specifications called for a rating of 112,500 gal. per min. (250 cu. ft. per sec.) delivered against a maximum head of 240 ft. In the discharge line of each pump is a hydraulic cylinder operated Dow pivot valve. The intake to each pumping unit can be shut off by a self-closing Treadwell gate, and each intake is equipped with vertical trash racks with air raking device. Provision is made for the insertion of stop logs in each pump intake, and in the two openings of the turbine draft tube.

*Electrical Equipment.* The generator is of the standard vertical water-wheel type with shaft end exciter. It is rated at 30,000 kv-a., 80 per cent power factor, 13,900 volts, 3-phase, 60 cycle, 200 rev. per min., with direct connected exciter rated at 154 kw., 250 volts, compound wound with interpoles. The pump prime movers are vertical synchronous motors rated at 7900 kv-a., 80 per cent leading power factor, 13,200 volt (with voltage range of 5 per cent above or below) 3-phase, 60 cycle, 327 rev. per min. Pump motor and spare excitation is furnished by two motor-generator sets each consisting of a 150 kw., 1200 rev. per min., 250 volt, compound wound d-c. generator with interpoles direct connected to a 225-hp., 220-volt, 3-phase, 60-cycle, squirrel-cage induction motor.

The shaft of the generating unit is of two sections, one for generator and one for turbine, with forged half flanged sections bolted together upon installation. The turbine shaft has one guide bearing of the babbitted type mounted on the turbine crown plate. Lubrication is provided from a self contained gear pump driven from the main shaft. For emergency operation a float controlled rotary d-c. motor driven auxiliary oil pump is provided. The generator shaft has a Kingsbury thrust bearing with copper cooling coils and an upper and lower guide bearing of the babbitted type. The lubricating system for the generator shaft bearings consists of a gear pump, driven from the main shaft and located in the lower guide bearing oil pan.

The shaft of the pumping units is one piece forged steel with a Kingsbury combined upper guide and thrust bearing with copper cooling coils mounted on the upper spider designed to support the total weight and thrust; and a guide bearing between motor and pump, supported in a cast iron frame of heavy section bolted at the bottom to the upper head of the pump. Lubrication of all bearings on each unit is automatic from a motor driven gear pump, with a similar pump for spare for each unit.

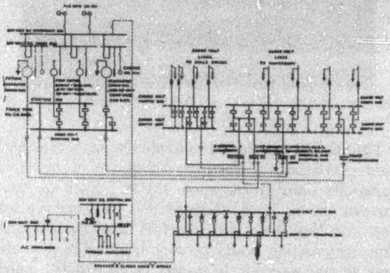

FIG. 8—SINGLE-LINE WIRING DIAGRAM OF ROCKY RIVER PLANT

*Station and Substation Equipment.* Under this heading there are five distinct groups:

a. 4600-volt indoor local distribution bus

b. 33,000-volt outdoor tie-in bus for Bulls Bridge station

c. 66,000-volt outdoor main station bus

d. 13,900-volt indoor bus for pumps

e. Station service busses.

A single line wiring diagram, Fig. 8, shows the general arrangements.

a. The 4600-volt bus is for distribution of power to the New Milford district. It was installed in the Rocky River power station so as to bring it under the supervision and control of the Rocky River power plant operators.

b. The 33,000-volt outdoor bus afforded the most economical arrangement for connecting the Bulls Bridge station (upstream from Rocky River about 8 mi.) to 66,000-volt main transmission system. At the same time this bus provides the means for later distribution of power, at a voltage higher than 4600 volts, to the more remote points of the New Milford district.

c. The 66,000-volt outdoor substation consists of a main and a transfer bus with switching equipment for the two 66,000-volt 3-phase lines to Waterbury, the 30,000-kv-a. transformer bank stepping down to 13,900 volts and the connection to the transformer banks stepping down to 33,000 volts and 4600 volts respectively. Space was left in the bus structure so that each of these two banks can be equipped with a separate circuit breaker. The 30,000-kv-a. main transformer bank has two oil circuit breakers, one of which acts as transfer breaker. Although the generating voltage is 13,900 volts the main station voltage is 66,000 volts. If it were not for the two pumping units there would be no bus and no switching equipment at 13,900 volts. As a matter of fact the second generating unit will be connected directly to its transformer bank as indicated on the wiring diagram in Fig. 8. The 66,000 volt side of the 30,000-kv-a. transformer bank is *Y*-connected and solidly grounded. The 13,900-volt windings are provided with 40, 50, and 60 per cent taps to obtain with an open-delta connection, approximately half voltage for starting the pumps.

d. The 13,900-volt indoor substation as mentioned above is for the sole purpose of supplying power to the pumping units. There are two busses, a full voltage running bus and a half voltage starting bus. The connections from the transformer bank to the busses are made with single conductor cables. The generator leads are connected to the running bus through a set of disconnecting switches with provision for a future oil circuit breaker. On the generator side of this tap is a non-automatic oil circuit breaker to disconnect the generator from the transformer bank before it is used to supply power to the pumps from the 66,000-volt bus. The two oil circuit breakers connecting each pumping unit to the starting and running busses are interlocked.

e. Station Service Busses. A 230-volt, 60-cycle, 3-phase bus supplies power primarily to the two motor-generator sets, the battery charging set, the sump pumps, air compressor, station lighting, etc. The main 250-volt, d-c. or exciter bus is, at present, divided into two sections, one for the generator, the other for the two pumps. The 250-volt d-c. emergency bus is supplied from one of the two motor-generator sets. The governor oil pump and the emergency turbine oil pump are normally connected to this bus; if power fails they are automatically switched over on to the 250-volt d-c. battery bus. All the control circuits and small d-c. motors in the plant are connected to the battery bus. The control battery was purchased large enough so that it can perform the double function of control battery and storage battery.

The fact that the plant is a peak load plant and that the pumps can be shut down for short periods without serious consequences and further that the generating unit is never operated at the same time as the pumps, made it possible to eliminate many duplications and reserve equipment which otherwise would have been necessary.

*Miscellaneous Equipment.* Inasmuch as part of the substructure of the plant is always below the water level in the Housatonic river, a sump was provided to collect any water which might possibly leak or seep into the basement. The sump is also connected to the draft tube of the generating unit and the intakes of the two pumps. All connections to the sump are controlled by hydraulically operated valves. Two 500-gal. per min. pumps are used for removing the water from the sump. An air compressor and pressure tank supply the air for the station, including the trash rack raking devices and the surge tank previously mentioned. Flow meters are installed to measure the water from the pumps and the water to the turbine. The water levels at the canal intake as well as in tail-race are recorded. Watthour meters record the output from the generator, the energy used by the pumps and for general station use.

The Rocky River development was designed and built by the U. G. I. Contracting Company of Philadelphia for the Connecticut Light and Power Company in close collaboration with the engineering staff of the Connecticut Light and Power Company.

### ADDITIONAL SUMMARY OF HYDRAULIC EQUIPMENT

*Main dam.* Length 952 ft., maximum distance from top to foundation 100 ft.

*Earth fill.* 367,800 cu. yd., 6 in. Wakefield core wall—31,000 sq. ft.

*Canal dike.* Length 2815 ft., earth fill, 332,000 cu. yd. 6 in. Wakefield core wall—52,000 sq. ft.

*Canal.* Length 3190 ft., excavation 708,200 cu. yd. Slope of sides generally 1 on 2 on cut side, 1 on 3 on dike side; Top elevation of dike 442 ft. Bottom 20 ft. wide at elev. 385 ft.

*Danbury dikes.* Earth fill, 59,000 cu. yd.

*Lanesville gap dike.* Earth fill, 18,000 cu. yd.

*North Lanesville spillway.* 175 cu. yd. concrete.

*South Lanesville spillway.* 742 cu. yd. concrete.

*Wood pipe line.* Approx. length 1007 ft., inside diameter 15 ft.; staves 4 in. by 6 in., tie rods ⅞ in. and 1 in. spaced 4 in. to 5¾ in.

*Steel penstock.* Approx. length 670 ft., inside diameter 13, 12, and 11 ft., thickness of steel plates ⅜ in. to ¾ in.

*Surge tank.* Johnson differential type. Shell diameter 28 ft., shell height 76 ft., riser diameter 9 ft., riser height 73 ft., orifices 4 ft. 4 in. diameter and 6 ft. 3 in. diameter.

*Dow pivot valves.* Diameter 54 in.—hydraulic cylinder operated.

*Sliding intake gate.* Self closing Broome gate 18 ft. 6 in. by 18 ft. 10 in. Opening 16 ft. diameter.

*Sliding suction intake gates.* Treadwell gate 6 ft. by 7 ft.

## Discussion

**P. M. Lincoln:** I should like to ask a question with regard to the last paper. There were certain figures which Mr. Amberg gave us on efficiencies reaching something over 100 per cent for certain conditions. I should like to ask whether or not those figures take account of evaporation. The matter of evaporation in a reservoir such as this where the water is stored over a period of years, must be a very important matter and must, of course, be considered carefully in the matter of calculating over-all efficiency. It strikes me the figures given are rather high, particularly if evaporation is to be considered.

**J. D. Justin:** I want to speak of Mr. Amberg's paper on the Rocky River Development. This development, due to its pumping feature, is entirely unique in America. However, in

Europe there have been some 35 or 40 plants that have been built along somewhat similar lines. One of these plants has a head of 540 ft., and there are two storage reservoirs. One of them is situated at the tail-water level and the other one forms the head-water with 540 ft. between them. The capacity of each reservoir is extremely small, only enough for daily operation. All this plant does at night when there isn't any peak load is to pump the water up in the reservoir at the top. Then over the peak-load period, the water comes down and goes through the turbines and produces energy on the peak of the load. The capacity of that plant is about 180,000 hp. There are 4 units, 45,000-hp. apiece. The pumps are somewhat larger than those at Rocky River and pump 640 cu. ft. of water a sec. each.

It seems to me rather remarkable that a plant like this, known as the Hengstey Plant in the Ruhr, Germany, would be economically justifiable in the heart of a coal region.

The capacity of the reservoir was less than 100,000,000 cu. ft.; in other words, about one-sixtieth of the capacity of the Rocky River reservoir.

I think there will be a good many more Rocky Rivers in America because there is an economic application for plants of this kind. In spite of all the advance in the steam plants, of mercury turbines and high-pressure units, there will still be some application for peak-load hydro plants where the cost of pumping for the high peak or the occasional peak would be a relatively small part of the alternate maintenance cost on the steam plant that would have to be provided to carry such peaks.

**C. L. Cate:** (communicated after adjournment) The Rocky River development goes further than the Swiss pumped-storage plants in that calculations have been based on using steam-generated power for pumping.

No data are given on the local storage at Bull's Bridge or Stevenson but with ordinary day-to-day pondage it is not clear how 50,000 kw. firm power is to be obtained from the three hydro plants as stated on the third page.

The author states that on the system of the Connecticut Light and Power Company there are no short-time peaks of any extent but that the system peak is the result of maximum 9-hr. day loads for which seasonal changes in load are responsible. This would indicate that during seasons of maximum load the load would be maintained at or near the peak for 9 hr. per day resulting in daily load factor of 37½ per cent on the hydro plants.

The 1914 hydrograph shows 6 months with an average run-off of about 0.3 cu. ft. per sec. per sq. mi. and 3 months with an average of 0.2 cu. ft. per sec. These figures would indicate maximum load factors of 20.4 per cent and 13.6 per cent respectively, at Bull's Bridge.

Corresponding figures for natural run-off at Stevenson would be 10.66 per cent and 7.1 per cent to which would be added water from the Rocky River plant operating at 37½ per cent load factor. This would increase the possible load factor at Stevenson by 13.6 per cent giving effective load factors of 24.26 per cent and 20.7 per cent which are both well below the 37½ per cent required. More water could be got to Stevenson by increasing the daily load factor at Rocky River but this would dissipate storage at a faster rate than allowed for in Mr. Amberg's calculations as given.

Fig. 5 shows on the lower curve representing present load a load factor of over 78 per cent for steam-generated power. If to this is added the steam required for pumping water the resulting load factor on the steam plant would apparently be over 90 per cent which seems somewhat high for a yearly load factor on steam equipment.

**E. J. Amberg:** In giving the figures for efficiencies and so forth, the very first thing we have done is to subtract from the run-off enough water to take care of evaporation. In other words, that 1,500,000,000 cu. ft. of water that we get in an average year from run-off is the net run-off after subtracting the run-off from 5 sq. mi. to take care of evaporation. We did that in order not to complicate the calculation of the studies afterward.

Now I want to add just a few words to what I said before in the application of such storage reservoirs. There are some advantages that can't be put down in dollars and cents. One advantage is that you have a generating unit which is instantly available in case of breakdown of another unit on the system. In a steam plant, to do that you have to carry additional turbine capacity and additional boilers on the line, and even then you can't always put on the machine quickly enough to save the shutdown.

There is another feature in the development. I showed 50 per cent of the load carried by the hydro plant. That is the basis we used for figuring and making sure that there was enough water under the extreme condition. In other words, if we had a load of 100,000 kw. we have 50,000 kw. in hydro units, we have 50,000 kw., let me call it, in active steam units and then we have 10,000 or 20,000 kw. in reserve steam units.

Now, in actual practise we would not operate 50,000 kw. of hydro capacity. We would operate first our steam units. In other words, we operate that so-called spare steam unit and keep our reserve in the hydro which of course would give us more leeway on that limited 24-hr. firm hydro capacity that we had. Instead of running the hydro capacity down to 50,000 kw. we would only run it down to 60,000 kw. (Fig. 5) which would probably take off 30 per cent of the energy that was in the shaded area and leave that much as an additional safeguard on the pumping scheme.

We have now on our system in Connecticut a load factor of 50 per cent which gives a fairly large base for the upper half of the load curve (Fig. 5). On account of the high system load factor we are limited in application to a 50-50 ratio between hydro and steam capacity. If the load factor on our system were only 35 per cent we could then with the same amount of primary hydro energy available develop more than 50,000 kw. in capacity. In other words we could obtain a ratio of say 60 to 40 as between hydro and steam or even better than that. From this it can be seen that systems with a lower annual load factor than we have could make a better use of such a pumped-storage development because they could install more hydro capacity and to that extent increase the value of the development over and above the value which it represents on the Connecticut Light and Power Company system.

Mr. Cate in his discussion points out that for the extreme condition of maximum system load and minimum flow of water in the river the Rocky River Plant will have to be operated beyond the 9-hr. period in order to release sufficient water for the Stevenson Plant to produce its full share of the load. This statement for the extreme condition is correct but I should not call it a dissipation of storage and it certainly is not dissipated faster than allowed for in our calculations. In studying load curves we also find that the maximum hour occurs only once a year and that even for the day of maximum hour the 9-hr. average is considerably less than the maximum hour. We further find that the average of the other days in the week which had the maximum peak is considerably below the maximum peak so that the matter is not as serious as it would appear when assuming that this maximum peak condition continues throughout a week or more. The answer to this particular problem is the duration load curve shown in Fig. 5 which indicates clearly that the high loads do not and cannot occur very frequently because the load drops off rapidly.

The distinction I wanted to make is between having 15-min. or half-hourly peaks scattered over many days or to have the same equivalent energy concentrated in a maximum week of the year as is the case on our system.

On account of the high loads being "bunched" in our case it is necessary to store the water from one season of the year to another.

Our calculations absolutely were figured to take care of the most extreme condition. This most extreme condition will happen only once in probably 50 years because it will require a coincidence of maximum output week and maximum peak load falling together; further it would require minimum river flow at the same time and it would further require that the reserve steam unit was out of commission. I have pointed out as one of the advantages of the hydro system the fact that under practical operating conditions the spare capacity would not be kept in the steam plant as assumed when making the study of this development but would be kept in the hydro plants and the spare steam unit would be actually used for daily operation. In this way the requirements on the hydro system would be very materially reduced.

Mr. Cate also questions the high load factor for the steam-generated power. In connection with this I simply want to call attention to the fact that this is the load factor of the power generated by steam but is not the station load factor because the reserve capacity is kept in the steam plant and if we compared the output of the steam plant based on 100 per cent use of its full installed capacity with the kilowatt-hours actually generated with the capacity actually required to carry the load we would obtain a station load factor which is considerably below that shown in the paper.

## THE APPLICATION OF RELAYS FOR THE PROTECTION OF POWER SYSTEM INTER-CONNECTIONS[1]

(L. N. Crichton and H. C. Graves, Jr.)

New Haven, Conn., May 9, 1928

**O. C. Traver:** The pilot wire scheme has been given a reasonably clean bill by Messrs. Crichton and Graves, although it is clear that the only important objection thereto is the cost of the pilot conductors. The exceedingly prompt action in case of internal faults and freedom from tripping on any external trouble is winning increasing favor in spite of this handicap.

For the longer transmission lines, carrier current may be a solution to the problem, as, by its use, we may secure a similar result without the need of the auxiliary wires connecting the two ends of the line, and I will try to give a crude mental picture of the principle of the carrier-current scheme as we are interested in it at Schenectady, and as it is being tried out by the Ohio Power Company at the present time. The plate supply of the oscillator is taken directly from the current transformer and accordingly oscillation can occur only on the positive half wave, and is transmitted half the time, that is, on each half cycle. At the receiving tube, the plate supply is again taken from the current-transformer secondary so that current can only flow through it each half cycle and then only if the grid potential permits. This grid is controlled by the carrier from the far end with the result that the plate current flows only in case the instantaneous directions of the main currents at the two ends of the line are alike, thus indicating a sound feeder. Under these conditions, the over-current relays are simply restrained from functioning.

Should a fault occur on the protected line and the instantaneous directions at the two ends, therefore, be in opposition, the receiving tube plate current would not flow, and the over-current relays would be free to trip the breaker. If this line should be down, short-circuited, or broken, so as to prevent the passage of the carrier, then the failure of the carrier to appear at the receiving end would leave the over-current relays free to operate and thereby give complete protection.

In other words, by simply matching the instantaneous direction of the currents at the two ends of the line, we can tell whether the current going in is also going out at the same time, under which condition we say it is all right, or whether it is flowing inward from both ends, which is all wrong, or whether by chance it is going in one end and the other end is passing nothing, in which case we can, and do, take out the end carrying any current worth considering. We can secure operation within ¼ sec. This quick action is of great importance as all operating engineers know. (For a full description, see "*A Carrier Current Pilot System of Transmission Line Protection*, by A. S. Fitzgerald, A. I. E. E. Quarterly Trans., Vol. 47, No. 1, Jan. 1928, p. 22.)

This paper indicates that many operating engineers hesitate about installing differential protection where many bushing-type current transformers must be connected in parallel in bus protection. Bushing transformers of the high ratio usually involved in such protection are generally as good as any.

I think there is no question of the more rapid action of balanced current protection as compared with impedance relays, so far as available equipment is concerned. Speed, again, is the important consideration, and balanced current relays have it. The impedance relay has a compensating advantage in that it can a little more simply care for the remaining single line.

The fault-detecting relay suggested by the authors involving two extra relays (over-current and undervoltage) does not seem as simple as one combining the two functions. Relays of the standard over-current type are available in which there is provided a voltage restraining action that simply changes the minimum operating current and leaves the time features as they were. This, of course, is in the nature of an impedance relay, but it is known by the descriptive name "Over-current-Undervoltage Relay." If, on a system, you need to care for a condition involving short circuits under light load conditions which are lower than the load currents at another time, this over-current-undervoltage relay will give the accustomed time characteristics but with a sliding current setting which is automatically adjusted by the system voltage.

In regard to the polyphase directional relay, I want to thank the authors for a very good defense of the practise which the General Electric Company has followed for some ten years back. We quite agree that the polyphase relay is a good one and hope they continue to make proper use of it.

I like the impedance-relay principle and believe more will be heard of it as conditions require, but the complication of Fig. 25 does not appear justified from any general point of view. Of the sixteen relay elements shown, the one ground relay can do from 90 to 95 per cent of the work. The table in Fig. 8, making its comparison on the basis of this unusual condition, is accordingly of very little value for the average system.

**L. N. Crichton:** Referring to Mr. Traver's discussion, the carrier-current relay protective scheme, which his company is interested in, is quite ingenious, and I am sure everyone is going to watch it with interest. It has a few disadvantages but so does every relay scheme, and I imagine it will be no harder, and perhaps easier to overcome those troubles than those of some other relay schemes.

The difficulty with bushing transformers for differential bus protection, mentioned in the paper, is something that has actually occurred on high-voltage transformers of a comparatively low ratio. There was quite a number of them in parallel, and it was found that if one of the transformers was dead, that is, the line was dead, the current from some of the other transformers would leak through it. Now, this was prevented in one case by putting auxiliary switches on the circuit breaker to cut out its transformer whenever the breaker was open. But this is bad because the switch may corrode or otherwise cause an open circuit and thus result in an unbalance which will cause improper operation.

There is not much doubt that any balanced relay will be a little faster than present impedance relays, but the difference in time will be small compared to the time required for the circuit breakers to open, that is, with present-day breakers. When making such comparisons it should be borne in mind that balanced schemes have their own troubles and objections.

Referring to the polyphase directional relay, there are not more than a half dozen systems in this country which demand its use. Most of the others can be served at least as well by the single-phase relay, maybe better.

All of us hope that there will not be many systems as complicated as that shown in Fig. 25 and Mr. Traver is correct in his statement that one of the relays shown will care for 90 to 95 per cent of the troubles. However, the remaining 10 or 5 per cent, or possibly less, must be cared for and the service is important enough to justify the extra relays. This installation is not the idea of one or two men but was chosen by a number of engineers intimately concerned with its success.

## OSCILLOGRAPH RECORDING OF TRANSMISSION LINE DISTURBANCES[1]

(J. W. Legg)

New Haven, Conn., May 9, 1928

**M. A. Rusher:** I should like to ask whether the twin vibrator element requires two air gaps in series or a single gap of greater width than that used with the standard vibrator element? Are the sensitivity and the natural frequency of this element the same as that of the standard oscillograph vibrator element?

I should also like to ask whether, in putting 15 records on one film, complication of records will not be introduced which will make it impossible to distinguish one curve from another?

It may be of interest in this connection that about ten years ago the General Electric Company built a 15-element oscillograph. The record used was over 12 in. wide and one of the main reasons for not building more of that type of oscillograph was that the records were difficult to read due to different curves running into each other.

I was also interested in the discussion with regard to the wattmeter elements for measuring power. For a number of years we have been using a three-phase oscillographic wattmeter for transmission-line tests. This instrument records the average power rather than instantaneous power as Mr. Legg's wattmeter element does, but it gives a record which is very easily read, one from which the average power at any instant can be obtained without calculation other than applying a single calibration. When operated in connection with other oscillographs we have found that the records from this wattmeter were of very great value.

**Alexander Dovjikov:** Setting aside the field of application of the cathode-ray oscillograph we feel that the requirements for automatic recording of system faults are satisfied to the greatest extent by the oscillographic type of instrument described by Mr. Legg. One of the most important features which makes these oscillographs particularly appropriate for the study of system transients is the introduction of oscillographic wattmeter elements—elements which measure power and power oscillations directly. A knowledge of the variations in this quantity is particularly valuable because it is the difference in power quantities that produce acceleration or deceleration of the machine rotors and eventually results in pull-out.

The combination of the flexible automatic features of the oscillograph equipment and the phase-sequence network for initiating and measuring quantities supplies the operating engineer with *quantitative facts* on which to base an intelligent analysis of the system operation. Interpreting the data obtained by reading the oscillograms, the necessary changes and adjustments in the system may be made; subsequent records would prove whether these changes and adjustments resulted in improvement.

**J. W. Legg:** I have been asked a number of questions about some of the details of the vibrator and other things. As to the twin vibrator galvanometer, used in the 3-Element Power Osiso and in the 15-element oscillograph, it has an air gap of 0.055 in. instead of the usual air gap of 0.030 in., still its sensitivity is twice that of the standard oscillograph vibrator, and it responds very well to 1000 cycles and thus beyond the range required for recording power transients. The sensitivity is more than one hundred times that of the Hall Recorder so that the power consumed is quite small.

As to 15 records on one film, I believe I limited that and said that in some cases 15 could be used. If the limit of speed is 10 in. in 10 sec., then 15 records would be quite confusing, especially if a very fine lens system were not used. However, on some of the tests we drive a 24-ft. film through in 4 or 5 sec. on which the cycles are spread way out, and then when 15 records are used, one can find every bit of the detail in every record. I have not seen any films yet with nine records in which one could not pick out every bit of the detail.

In three-phase lines, the three voltages will be just out of phase with one another, and even though they all have the same zero, each wave is perfectly free, provided you have a reasonable speed of film. Of course, 10 in. in 10 sec. would cause considerable confusion with 15 records. I have one lantern slide that appears to show some interference; however, the original record is clear.

Now, there is the question of the instantaneous wattmeter versus the average-value wattmeter. Our company carried on tests for a number of years with the average-value wattmeter, both polyphase and single-phase. We have made a small average-power polyphase wattmeter which one can carry in the palm of one's hand. But for the most part, the instantaneous values of power are much preferable. All galvanometers occupy about the same space and are freely interchangeable in these oscillographs.

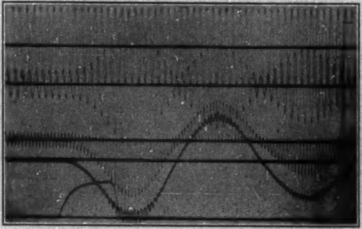

Fig. 1

In our 15-element oscillograph, the records are all in the same time-phase relation. This is not an improvised oscillograph. Previous ones were in reality a combination of several oscillographs, with one tier above the other, so that the light beams crossed at the cylindrical lens and reached the film half in one height and half in another, and thus gave a different time relation on the film. All fifteen of our records are in exact time-phase relationship, and easily controlled.

Many of the lantern slides shown when the paper was presented at New Haven were of oscillograms which were not available at the time the paper was written. The publication herewith of one showing a power surge recorded with a single-phase and polyphase instantaneous wattmeter should be more convincing than a lengthy written discussion.

The lower record is the short-circuit current of the d-c. end of a large motor-generator set. The one above this is of polyphase instantaneous watts, showing the surge of power from line to alternator, alternator to line, and so on. The record above that is single-phase instantaneous watts showing the changing power factor and kilovolt-amperes as well as giving a good idea of the surge of average power. The frequency here is twice that of the fundamental current or 120 cycles per sec. The record above shows instantaneous values of the a-c. in one line. The one above this, the top one, shows the instantaneous values of alternating potential in phase with the current when the power factor is unity. A comparison of the upper three waves will show the current lagging 90 deg. for zero power factor, lagging 180 deg. for minus unity power factor (when alternator is taking maximum power from line), and in phase with current when power factor is unity. However, the single-phase instantaneous watt curve tells a greater story than any other one record.

# Symposium on Surge Voltage Investigations

## Surge Voltage Investigation on Transmission Lines

BY W. W. LEWIS*

Member, A. I. E. E.

***Synopsis.**—This paper and companion papers discuss the surge voltage investigation on six power systems in the lightning season of 1927.*

*Valuable data have been secured as to the nature and polarity, magnitude, wave-front and attenuation of surges, also the effect of overhead ground wires, choke coils, and lightning arresters.*

*Especially interesting is the attenuation formula $A = k\,e^s$, the form of which indicates a close connection between attenuation and corona loss.*

*Further investigations are being carried on in the present year to secure more complete and exact data on wave shape and attenuation, effect of ground wires, lightning arresters, and choke coils.*

---

IN 1926 the General Electric Company conducted a surge voltage investigation on a limited scale in cooperation with the Pennsylvania Power & Light Company, New England Power Company, and Consumers Power Company. Thirty surge-voltage recorders in all were used. In 1927 the investigation was continued with a larger number of instruments on the systems mentioned, and some additional systems were included, namely, the Ohio Power Company, Alabama Power Company, and New York Power & Light Corporation. In all 130 instruments were in service.

This investigation yielded a vast amount of data, which has been sifted and analyzed, and it is the purpose of this and the companion papers[1] to present the more important data and the conclusions to be derived therefrom.

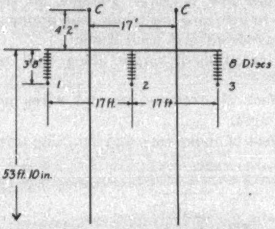

FIG. 1—DIAGRAM OF THE STANDARD TWO-POLE TOWER STRUCTURE USED ON THE LOCK 18—HATTIESBURG 110-KV. LINE OF THE ALABAMA POWER COMPANY

The wires marked *C* are the insulated communication circuits

The companion papers present in considerable detail a description of the system and the results of the investigation as far as the Pennsylvania Power & Light Company, New England Power Company, Ohio Power Company, and Consumers Power Company systems are concerned. The investigation on the Alabama Power Company and New York Power & Light Corporation's systems was not so extensive as on the other systems mentioned. Some data were obtained however, and these will be included in the present paper. A brief description of these two installations follows.

### ALABAMA POWER COMPANY INSTALLATION

The 110-kv. transmission line extending from Lock 18 power plant in Alabama to Hattiesburg, Mississippi, was under investigation. This is a single-circuit line on wooden pole *H* frame construction, Fig. 1. The design characteristics of the line are given in Table I.

Fig. 2 shows diagrammatically the arrangement of the conductors and the communication wires. The communication wires are transposed between stations as indicated. They are insulated by means of porcelain pin type insulators, nominally rated 23 kv. The communication circuits terminate at the various stations in insulating transformers, with their mid-point grounded. The pins of the insulators of the communication wires, as well as the crossarms supporting the line conductors, are grounded at each tower.

Fig. 2 also shows the location of the surge-voltage recorders. Fig. 3 is a typical surge-voltage recorder installation.

### NEW YORK POWER & LIGHT CORPORATION INSTALLATION

A small portion of the 110-kv. and 33-kv. system of this company was under investigation. Fig. 4 shows this portion of the system and the location of the surge-voltage recorders. Table II gives the principal design characteristics. Fig. 5 shows a typical recorder installation.

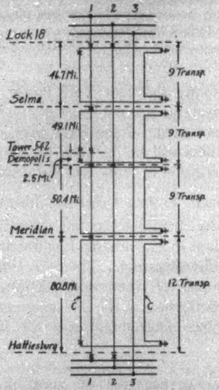

FIG. 2—ARRANGEMENT OF POWER CONDUCTORS AND COMMUNICATION WIRES ON LOCK 18—HATTIESBURG 110-KV. LINE OF THE ALABAMA POWER COMPANY

The power conductors are not transposed. The communication circuits are transposed frequently, the number of transpositions between stations being indicated on the diagram. To avoid confusion, the transpositions are not shown on the diagram. The location of the surge-voltage recorders is indicated by the symbol X.

### PURPOSE OF INVESTIGATION

The surge voltage investigation was conducted for the purpose of securing information on the following subjects:

FIG. 3—TYPICAL SURGE RECORDER INSTALLATION, ALABAMA POWER COMPANY

1. Nature and polarity of surges,
2. Magnitude of surge voltages on transmission lines due to lightning, switching, and arcing grounds,
3. Wave-front and wave-shape,
4. Attenuation of surges along the transmission line,
5. Effect of overhead ground wires in reducing surge voltages,
6. Effect of choke coils and lightning arresters.

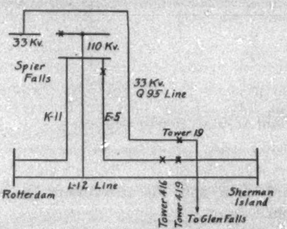

FIG. 4—PORTION OF NEW YORK POWER & LIGHT CORPORATION'S 110- AND 33-KV. SYSTEM

Surge-voltage recorder stations indicated by symbol X

Each of these items will be discussed in more or less detail.

*1. Nature and Polarity of Surges.*

Surges may be classified as unidirectional and oscillatory. The unidirectional surges may be positive or negative.

The oscillatory surges may be further classified as highly damped *H D,* medium damped *M D,* and slightly damped *S D.* A highly damped figure may be predominately positive or negative.

The *H D* figures are interpreted as being produced by a surge voltage which lasts for only a few polarity reversals, say less than five.

FIG. 5—TYPICAL SURGE RECORDER STATION, NEW YORK POWER & LIGHT CORPORATION

The *M D* figures are attributed to oscillations following flashovers between line conductor and ground. They appeared in this investigation only on the Consumers Power system, which was the only isolated neutral system in the investigation.

TABLE III
POLARITY OF LIGHTNING SURGES

| | Unidirectional | | | | Oscillatory* | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|
| | Positive | | Negative | | Positive | | Negative | | Equal | | |
| System | No. | Times Nor. | No. | Times Nor. | No. | Times Nor. | No. | Times Nor. | No. | Times Nor. | Remarks |

| New England Power Co. | 8 | 1.7 | 11 | 3.0 | 21 | 7.4 | 39 | 10.0 | 25 | 6.9 | See note |
| Consumers Power Co. | 1 | 1.9 | 3 | 1.2 | 28 | 8.4 | 20 | 7.5 | 24 | 10.0 | |
| Alabama Power Co. | 1 | 1.3 | 3 | 2.2 | 4 | 2.6 | 4 | 6.8 | 15 | 4.5 | |
| New York Power & Light Corp. | 14 | 1.8 | 10 | 1.7 | 13 | 2.3 | 15 | 6.9 | 19 | 7.3 | All surges |
| Weighted total | 65 | 234 | 60 | 120 | 77 | 559 | 89 | 807 | 104 | 864 | |
| Average | | 3.6 | | 2.0 | | 7.25 | | 9.1 | | 8.3 | |
| Note: If surges are classed as to polarity at place where magnitude of surge was highest, following will result: | | | | | | | | | | | |
| New England Power Co. | 18 | 2.4 | 30 | 10.0 | 11 | 7.6 | 21 | 8.4 | 24 | 6.9 | |

*Classified as to whether surge is predominantly positive or negative, or with positive and negative equal.

The *S D* figures are of uncertain origin. They appear to be formed from a continuous application of a-c. potential for a duration of several seconds. They are thought to be connected with a particular potentiometer arrangement, as they did not appear when simultaneous records were taken with other potentiometer arrangements.

Examples of figures produced by the various classes of surges are given in Fig. 6 of this paper, and examples of *H D* and *S D* figures are also given in Lee and Foust's paper.[3]

Table III gives a summary of the lightning surges on the various systems classified as to polarity. All surges given as unidirectional were of the same polarity throughout at all stations where they were measured. Surge voltages given as oscillatory registered with both positive and negative polarity values at one or more stations, but many of these registered as unidirectional on some recorders. The generally low magnitude of the unidirectional surges shown by the table must be interpreted with this explanation in view. Unidirectional surges of high magnitude were obtained at some stations, but if the surge showed an oscillatory character at any other station, it was classed as oscillatory.

In the case of the New England Power Company a second classification is given in the table, in which the polarity is taken at the place where the magnitude of the surge was the highest. Classified in this manner the results appear somewhat different from the first classification.

The second classification is probably as reasonable as the first one. It is impossible in this study to separate the lightning surge from the switching surge which follows in case the line trips-out.

### 2. *Magnitude of Surge Voltages on Transmission Lines due to Lightning, Switching, and Arcing Grounds.*

*a. Lightning.* In Table IV are listed the maximum voltages due to lightning, first, all figures and second, *H D* figures only. In this table are also listed the number of disks, type, and impulse flashover of the line insulators as determined in laboratory tests.[4]

It will be noted that the maximum voltage recorded in no case exceeds the impulse flashover values given, but is in most cases comparable in value or somewhat less. This would indicate that the impulse values given are fair values to use in estimating the lightning

TABLE IV
MAXIMUM VOLTAGE DUE TO LIGHTNING

| | Max. voltage | | Line insulation | | | Ht. of line | |
|---|---|---|---|---|---|---|---|
| | All figures | *HD* figures | Disks | Type | Impulse flashover kv. | At tower | Average ht. top cond. |
| Ohio Power Co | 1200 | 475 | 10–11–12 | OB–25622 | 1180–1400 | 60–73–86 | 70 |
| Pa. Pr. & Lt. Co | 2100 | 1800 | 14–16 | Locke 7500 | 1900–2140 | 66 | 50 |

d. Slightly damped surge

flashover of transmission lines, and would further indicate that the maximum voltage induced on a line is limited by the insulator flashover.

In this table are also given the height of the lines at the tower and an estimated average height of the top conductor, also the kv. per ft. of height based on the maximum voltage for all classes of figures. The kv. per ft. of height required for flashover is given, based on the longest string listed. It will be noted in the last column of the table that voltages have been recorded from 52 to 98 per cent of the flashover value.

In most cases it is probable that the recorders were not located at the point of highest voltage. Also, it is possible that flashovers occur at much lower values than given in the table, which are based on a certain wave of very steep front. In practise the waves may be considerably less steep and otherwise different in shape.

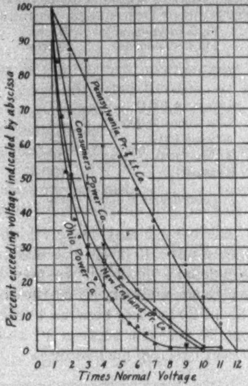

Fig. 7—Magnitude of Surge Voltages Due to Lightning on the Various Power Systems

Fig. 7 shows curves of surge voltages due to lightning for the various systems. In these curves the abcissas represent times normal crest to neutral volts, and the ordinates per cent of the total number exceeding the value indicated by the abcissas. All surges, *H D*, *M D*, and *S D*, have been grouped in these curves.

TABLE V
MAXIMUM VOLTAGE DUE TO SWITCHING

| System | Normal voltage crest kv. to neutral | Energizing times normal kv. | Deenergizing times normal kv. | Both times normal kv. |
|---|---|---|---|---|
| Ohio Power Co. | 108 | 4.2 | 5.2 | |
| Pa. Pr. & Lt. Co. | 180 | 4.0* | Less | |
| N. E. Pr. Co. | 90 | .. | .. | 4.0 |
| Cons. Pr. Co. | 114 | 3.0 | 3.6 | |
| Alabama Pr. Co. | 90 | 1.5 | 2.6 | |
| New York Pr. & Lt. Corp. | 90 | Less | 3.4 | |
| Average | | 3.2 | 3.7 | |

*On this system all switching was done on the low tension side.

It will be noted that the curves have the same general shape and that the majority of surges are of low value, *i. e.,* less than five times normal.

*b. Switching.* Table V gives the maximum voltages due to switching classified as to energizing and deenergizing lines.

It will be noted that deenergizing is slightly more severe than energizing.

Switching load on and off gives a very mild overvoltage disturbance, for example, 1.2 times normal on the Ohio Power Company's system.

The conclusions as to the relative severity of the various types of switching agree with conclusions arrived at previously with the oscillograph,[5] although the magnitudes recorded by the surge-voltage recorder are much greater than by the oscillograph.

In Fig. 8 are shown curves of switching surges for three systems, the abscissas representing the number of times normal and the ordinates representing percentage of all surges exceeding the given number of times normal shown on the abcissas.

It will be noted from these curves that the majority of all switching surges were less than three times normal.

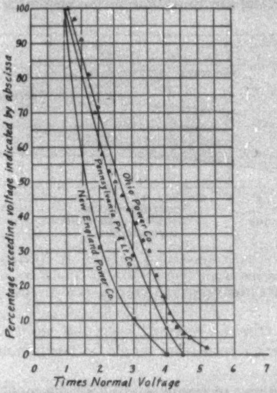

Fig. 8—Magnitude of Switching Surges on Various Systems

In these surges *H D* figures predominated. They were very general throughout a system, that is, they appeared at all the recorder stations and at practically the same value.

*c. Arcing Grounds.* It is not possible from this investigation to separate lightning surges from the arcing ground or switching surges which follow in many cases. The initial surge caused by lightning and the subsequent surges due to arcing grounds or switching are shown as one surge by the recorder.

The Consumers Power Company is the only one of the systems operating with an isolated neutral, and therefore the only one subject to overvoltage due to arcing grounds. It is possible that the *M D* figures found only on this system were caused by arcing grounds. Pure *M D* figures were found of a magnitude of 7.7 times normal. Such *M D* figures recorded on practically all instruments on the system and in some cases were coincident with switch trip-outs due to the operation of ground relays. In other cases the *M D* figures appeared coincidentally with system disturbances caused by arcing from the line wire to a tree. This incident accounted for five surges ranging from 2.5 to 3.6 normal times. Theoretically the maximum voltage that can be obtained from arcing grounds is about six times normal.[6]

*d. General.* From the data given it may be concluded that a transmission line insulated for about six times normal voltage, will be fairly safe from flashover due to switching or arcing grounds. The average system is insulated for this voltage or better.[6] The average system is also insulated for impulse voltages of 10 to 14 times normal.[4]

Since only a fraction of the voltages recorded reach the extreme value of 10 to 14 times normal on impulse (Fig. 7) and six times normal on switching or arcing grounds (Fig. 8), it would seem that most of the lines with average insulation should be fairly immune from flashover.

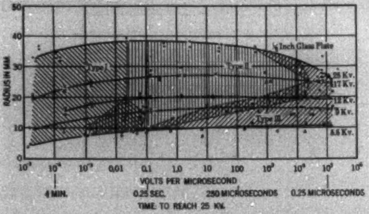

FIG. 9—CHART SHOWING VARIATION OF POSITIVE LICHTENBERG FIGURES WITH CREST VOLTAGE AND RATE OF VOLTAGE RISE, AND CLASSIFYING THE FIGURES INTO TYPES

That many of the lines are not so immune indicates that our data on the line insulation may not be exact, or our data as to voltage magnitude not complete. Then again, we know very little about the behavior of direct strokes.

### 3. *Wave-Front and Wave-Shape.*

Up to the present time we have not been able to obtain any data on the shape of the waves encountered on transmission lines. Some data as to the front of the wave have been obtained by inspection of Lichtenberg figures. The method is as follows: The figure is examined as to type and magnitude. This locates the surge somewhere within wide limits by means of the chart, Fig. 9, reproduced from Mr. K. B. McEachron's A. I. E. E. paper.[2] If the surge appears at another station on the system, it may appear with a different magnitude and slope and perhaps be of a different type. Thus, it is possible by inspection of figures of the same surge appearing at two or more stations, to establish the time of the front within wide limits.

Mr. K. B. McEachron has examined the records of about 150 figures in this manner. The results of this study are shown in Table VI. It will be noted from this table that only one figure definitely indicated a front less than one microsecond, although some of those classed as less than 10 microseconds may also be less than 1.0 microsecond, likewise for those classed as less than 100 and 100,000 microseconds. Those classed as at least 1.0 microsecond may be anything over 1.0 microsecond, even up to 10 or 100 microseconds.

TABLE VI
TIME OF FRONT OF WAVE AS INDICATED BY INSPECTION OF LICHTENBERG FIGURES

| Time to reach crest in microseconds | No. of figures |
|---|---|
| Less than 1.0 | 1 |
| Less than 10.0 | 1 |
| Less than 100.0 | 11 |
| Less than 100,000 | 44 |
| At least 100.0 | 48 |
| At least 10.0 | 16 |
| At least 1.0 | 33 |
| Total figures | 154 |

From this indefinite grouping, we may make the following very rough summary as to the duration of wave-front: about 20 per cent between 1 and 10 microseconds, about 20 per cent between 10 and 100 and about 60 per cent over 100 microseconds.

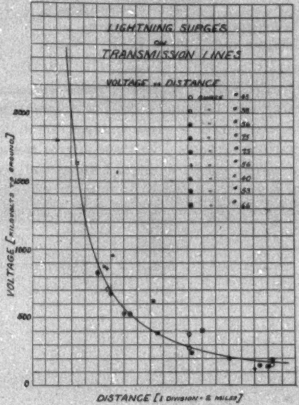

FIG. 10—CURVE SHOWING VARIATION OF VOLTAGE WITH DISTANCE FOR VARIOUS SURGES

Surges 38 and 40 are on Pennsylvania Power & Light Company's system, all others on New England Power system.

There is some indication from this study, that the waves of highest magnitude are also the steepest.

### 4. *Attenuation of the Surges along the Transmission Line.*

C. M. Foust and F. B. Menger have plotted a number of surges (Fig. 10) which appeared at more than one station, with distance from an assumed origin as abscissas and voltage as ordinates. They then drew an average curve and determined equations for the variation of voltage with distance, and the rate of change of voltage with distance or attenuation. These equations are as follows:

$$e = \frac{e_0}{k\, l\, e_0 + 1} \qquad (1)$$

$$A = -\, k\, e^2 \qquad (2)$$

in which

$e_0$ = the initial voltage at the point where the surge originated

$k$ = a proportionality factor which is found empirically

$l$ = the distance in miles from the origin of the surge

$e$ = voltage at any distance $l$

$A$ = the attenuation in kilovolts per mile.

The factor $k$ for all the surges investigated has been found to be about 0.00016.

These equations are used as in the following examples:

1. Assume the initial potential to be 2000 kv. Then at a distance 10 mi. from the origin:

$$e = \frac{2000}{(0.00016 \times 10 \times 2000) + 1} = 477 \text{ kv.}$$

The attenuation at the point of origin of the surge is

$$A = -\,0.00016 \times 2000^2$$
$$= -\,640 \text{ kv. per mi.}$$

2. If the initial surge was only 1000 kv. in magnitude, then the attenuation would be

$$A = -\,0.00016 \times 1000^2$$
$$= -\,160 \text{ kv. per mi.}$$

As a limiting case for any line, the flashover value of the line insulation may be taken as the initial voltage.

Equations (1) and (2) have a great deal of significance They state that the voltage varies inversely as the distance and that the attenuation varies as the square of the voltage. Since attenuation depends on resistance loss in the conductor and corona loss, and since it is known that resistance loss accounts for only a small amount of attenuation, the greater part of it must be due to corona loss. Corona loss varies as the square of the voltage, so that the attenuation, Equation (2), seems to tie in with the corona loss. The factor $k$ probably varies with the size and spacing of the conductors on the transmission line, but for the various lines in this study the average of 0.00016 gave results which agree fairly well with the test data.

It seems likely that the particular units chosen for distance and potential have more effect on $k$ than anything else. In our case we have used miles and kilovolts. If other units were used, such as absolute units, a different value for $k$ would result. More data and more study may serve to refine this factor somewhat. Equations (1) and (2) are plotted in curve form in Fig. 11, assuming initial voltage $e_0$ = 1000 kv.

In this figure attenuation has been plotted for convenience as positive, although it will be noted from Equation (2) that it is a negative function.

The following example served as a useful check on the formulas: Surge No. 75 on the New England Power system gave readings at several stations. Assuming the voltage at the origin to be 1000 kv. (the estimated flashover value of the line insulators) the distance to the origin from one of the stations was computed and found to be 25 mi. Visual inspection indicated a flashover at 21.5 mi. from the station.

### 5. *Effect of Overhead Ground Wires in Reducing Surge Voltages.*

The ground wire data are rather inconclusive, mainly because of a lack of exact comparison between lines with and without ground wires, and also because of the effect of reflections. The surge-voltage recorder measures the maximum voltage regardless of whether the maximum is the initial voltage or the reflected voltage. Nevertheless the data have given a few indications of the effect of the ground wire.

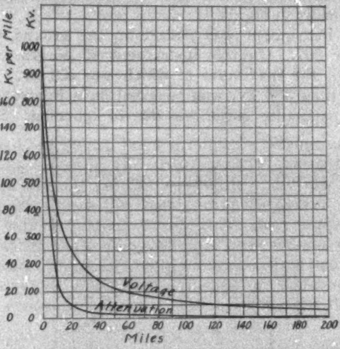

Fig. 11—Variation of Voltage with Distance and Rate of Decrease of Voltage with Distance, from Equations (1) and (2). Initial Voltage 1000 Kv.

*a. Ohio Power Company's System.* Approximately 50 surges were measured simultaneously on top, middle, and bottom conductors of the vertically arranged circuit. This line is a double circuit line with one overhead ground wire above and midway between the two circuits. In Table VII is given the theoretical potential of the three conductors without ground wire, expressed in per cent, on the assumption that the bottom conductor is 100 per cent and that the other conductors have potentials proportional to their heights above ground. Then there is given the theoretical potential with ground wire, still assuming that the bottom conductor is 100 per cent and using the protective ratios given in Reference 4, *i. e.*, 0.42, 0.52, and 0.62, for top, bottom, and lower conductors respectively. Finally is given the average of the surge-voltage recorder readings expressed in per cent, with the bottom conductor as 100 per cent.

The order of the actual protection agrees with the theoretical, but is not so favorable as the theoretical based on ideal conditions. The results are illustrated graphically in Fig. 12.

TABLE VII
EFFECT OF OVERHEAD GROUND WIRE
OHIO POWER CO.

| Conductor | Approx. height at tower—ft. | Theoretical potential without ground wire per cent | Theoretical potential with ground wire* per cent | Measured potential with ground wire. Average of readings per cent |
|---|---|---|---|---|
| Top........ | 85 | 143 | 68 | 89 |
| Middle..... | 72 | 121 | 84 | 98 |
| Bottom.... | 59 | 100 | 100 | 100 |

*Calculated by means of tables in Reference 4.

An instrument was placed on the ground wire at Tower 297. On this instrument 65 surges were recorded, the maximum of which was 8.2 kv. At the same time 380 kv. was recorded on a line conductor. This particular surge was due to lightning. Seventy per cent of all the surges were over 3 kv. Many of the surges were tied up with switching on the transmission lines.

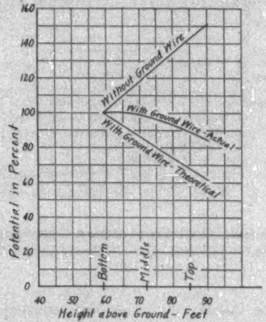

FIG. 12—GROUND WIRE PROTECTION, OHIO POWER COMPANY'S SYSTEM

*b. Pennsylvania Power & Light Company's System.* This 65-mi. line is equipped with 20 mi. of ground wire at the Wallenpaupack end and four mi. at the Siegfried end.

There were three periods of operation in 1927, (1) without ground wire, that is up to May 24, (2) period of installing ground wire, line not energized, May 24 to July 24, and (3) with ground wire, after July 24.

Any readings taken on the portion of the line not covered by ground wire are subject to reflection at the junction between the covered and not covered portions. Likewise the portions under the ground wire are subject to reflection at the terminals. All we can look for, therefore, is a tendency or trend.

For the period after the ground wire was installed a curve was drawn showing the highest values of surges recorded at stations along the line, and the average values of the surges recorded at the stations. The average of the highest values and the average of the averages were then taken for the unprotected portion of the line and for the protected portions. Table VIII shows the averages.

TABLE VIII
EFFECT OF OVERHEAD GROUND WIRE
PENNSYLVANIA POWER & LIGHT CO.

| | Unprotected | | Protected by ground wire | | | |

*From reference 4.

*c. New England Power System.* On this system the transmission line under test consisted of two circuits horizontally arranged. The conductors may be designated 1, 2, 3, 4, 5, 6. There was one ground wire above and between conductors 2 and 3. Instruments were installed on all six conductors at two places, Griswoldville and Barre. The readings on these instruments did not necessarily indicate the potential due to the conductor position at that point, because the conductors were frequently transposed. The fairest attempt to evaluate the effect of the ground wire was to select those surges which had their highest values at one of the stations, and therefore presumably originated near that station. For this purpose five surges which had their highest value at Barre were selected. The readings are given in Table IX.

TABLE IX
EFFECT OF OVERHEAD GROUND WIRE—NEW ENGLAND POWER CO. SURGE VOLTAGES HAVING THEIR HIGHEST VALUE AT BARRE

| Surge no. | Conductor position Number of times normal | | | | | |
|---|---|---|---|---|---|---|
| | 1 | 2 | 3 | 4 | 5 | 6 |
| 59............ | 5.2 | 3.9 | 3.3 | 2.2 | 4.2 | 4.2 |
| 66............ | 9.0 | 3.9 | 6.5 | 3.8 | 6.0 | 6.1 |
| 88............ | 3.1 | 2.5 | 4.0 | 2.8 | 3.5 | 5.3 |

| 114........... | 4.0 | 2.8 | 3.9 | 5.0 | 5.5 | 8.3 |
| Average....... | 4.8 | 3.1 | 4.2 | 3.3 | 4.4 | 6.4 |
| Per cent....... | 75 | 48 | 66 | 52 | 69 | 100 |
| Theoretical per cent*........ | 74 | 64 | 64 | 74 | 89 | 100 |

*From Reference 4.
Ground wire above and between conductors 2 and 3.

It will be noted that these readings are not entirely consistent, sometimes one conductor being highest and sometimes another. The averages of the five surges are plotted in Fig. 13. The averages of the readings expressed in per cent agree fairly well with the theoretical protection to be expected.[4] Fig. 13 also shows the number of flashovers that took place in 1927 on the various conductors at all parts of the line, as indicated by a visual inspection. A somewhat irregular flashover curve is to be expected, because under the worst conditions the ground wire would only reduce the potential on the most favored conductors to about 2000 kv. and the other conductors would have higher potentials. This potential is about twice the flashover value of the insulators, and it is a matter of chance which conductor spills over.

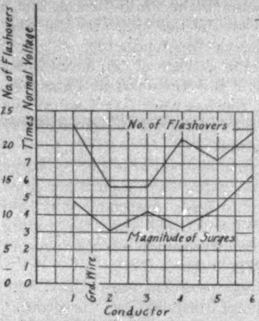

FIG. 13—POTENTIAL MEASURED ON VARIOUS CONDUCTORS AND FLASHOVERS OBSERVED, NEW ENGLAND POWER COMPANY

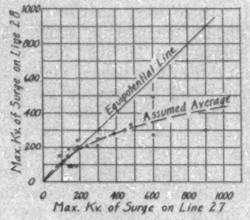

FIG. 14—GROUND WIRE PROTECTION, NEW ENGLAND POWER COMPANY, AS INDICATED BY READINGS AT GRISWOLDVILLE

Another effort to evaluate the effect of the ground wire has been made by plotting the highest crest value of lightning surges on line 27 (without ground wire) as abscissas and the highest values on line 28 (with ground wire) as ordinates. A reference line at 45 deg. is drawn to assist in interpreting the results. Fig. 14 shows the points plotted from the readings taken at Griswoldville and Fig. 15 at Barre. An average curve drawn through these points assumes a general drooping shape indicating the beneficial effect of the ground wire. This is more apparent on the readings at Griswoldville (Fig. 14) than those at Barre (Fig. 15).

*d. Consumers Power Company.* On this system there were two lines under investigation, the *H*-8 and *K*-11 lines between Saginaw River and Flint. These lines were on separate structures and in some cases as much as 10 mi. apart, being in multiple, however, at the two ends. During the entire season the *H*-8 line operated without ground wire while the *K*-11 had a ground wire during the latter part of the season.

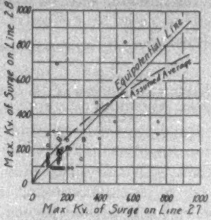

FIG. 15—GROUND WIRE PROTECTION, NEW ENGLAND POWER COMPANY, AS INDICATED BY READINGS AT BARRE

For various reasons it is difficult to compare the performance of the *H*-8 and *K*-11 lines. Some of the reasons are: difference in tower height and configuration of conductors, difference in insulation, difference in size of conductor, also the fact that lines are tied together at ends and to other lines on which the trouble may originate. It is also difficult to compare the performance of the *K*-11 line before the ground wire was installed and after, because comparatively few high voltage surges were recorded, and very few of them before the ground wire was installed. About the only thing we can do is to compare the maximum potential on the two lines before and after the ground wire was installed, and also to compare the maximum obtained on the three conductors of the *K*-11 line before and after the installation of the ground wire. This is done in Table X. The results show a slightly lower maximum potential on the *K*-11 line after the ground wire was installed,

TABLE X
CONSUMERS POWER CO. HIGHEST POTENTIALS OBTAINED BEFORE AND AFTER GROUND WIRE WAS INSTALLED ON *K*-11 LINE

| Line | Before ground wire installed times normal | After ground wire installed times normal |
|---|---|---|
| *H*-8 | 9 | 10 |
| *K*-11 | 9 | 8 |
| *K*-11 Top | 8 | 6 |
| Middle | 9 | 8 |
| Bottom | 7.7 | 5.9 |

while at the same time the H-8 line, which had no ground wire, showed a slightly higher potential.

On the ground wire itself a number of surges was measured at tower 318 and midway between towers 318 and 319. The results of these readings are shown in Table XI.

In only one case was any potential indicated at the tower. The potential at the mid-span varied from 2 to something over 35 kv. All these potentials are small compared with the potential on the line conductor, and indicate that the ground wire is maintained near enough to ground potential to be effective in performing its protective function..

TABLE XI
CONSUMERS POWER CO.
POTENTIAL MEASURED ON GROUND WIRE
Kv. Crest

| Surge no. | At mid-span towers 318 and 319 | At tower 318 | On conductor at tower 318 |
|---|---|---|---|
| 116 | 35 + | 28 | 206 |
| 166 | 24 | 0 | 456 |
| 146 | 6 | 0 | 410 |
| 148.1 | 5.5 | 0 | .. |
| 87 | 3.7 | 0 | 850 |
| 94 | 2. | 0 | 205 |

*e. Alabama Power Company.* As described previously, this is a single circuit line with conductors horizontally arranged and two lightly insulated overhead communication wires, which are connected to ground through transformers at the stations. Fig. 16 shows a comparison between the potential on the middle conductor as abcissas and the potential on one of the outside conductors as ordinates. A 45-deg. line is plotted for reference. It will be noted that there are more points above the 45-deg. line than below, indicating that the outside phase is subject more to high voltage than the middle conductor.

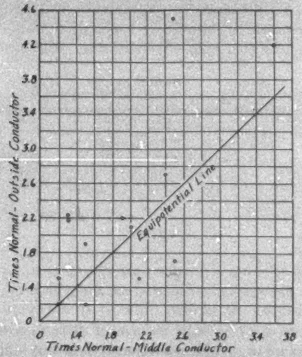

FIG. 16—COMPARISON BETWEEN POTENTIAL ON MIDDLE AND OUTSIDE CONDUCTORS, ALABAMA POWER COMPANY

On the insulated communication wire itself surges were recorded varying from 120 to 170 kv. As would be expected, these figures indicate that this wire is not kept as near ground potential as a wire which is connected to ground at each tower. Such an insulated wire should therefore not offer as effective protection as a wire more thoroughly connected to ground.

### 6. *Effect of Choke Coils and Lightning Arresters.*

At both ends of the Philo-Canton line, instruments were placed on the bus side and the line side of the choke coils on the top conductor.

Based on the average of ten simultaneous readings, the line side of the choke coil at Philo was 15 per cent higher than the bus side. At Canton the average of 12 readings showed the line side to be six per cent higher than the bus side.

It is not possible to say whether the surges originated on the Philo-Canton line or on other lines tied to the Philo or Canton bus. Assuming that they originated on the Philo-Canton line then the averages obtained indicate a small reflection of the incoming surges at the choke coils.

Surge-voltage recorders were placed across about 12 ohms resistance, installed in the ground or neutral end of the four-stack oxide film arresters at Canton, Newcomerstown, Philo, and Turner. Only two instruments gave records, those at Newcomerstown and Turner. Both switching and lightning surges apparently cause discharges, although the majority were tied in with lightning.

The current measurements varied from 150 to 2620 amperes. One reading was 1260 amperes, one 2620, and the balance were below 450 amperes.

On this system there were 97 highly damped lightning surges recorded. Of these only four were above two times normal. There were also 69 lightning surges classified as slightly damped, of which 31 were over three times normal and 18 over four times normal. Probably about three times normal is required between line and ground before the arrester gaps arc over, on account of the gap setting and the division of voltage between gap and arrester stack. The fact that only about one-fifth of all the surges recorded as due to lightning were over three times normal, and that not all of these were highest in the vicinity of the arresters, may account for the comparatively few readings of arrester discharge taken during the summer.

## CONCLUSIONS

Some surge voltages due to lightning are unidirectional and some are oscillatory. Of the unidirectional surge voltages, some are positive and some are negative. Of the oscillatory surge voltages, some have positive characteristics predominating and some have negative.

While there may be a trend in some systems toward certain polarity characteristics, the surge voltages recorded on these systems are not exclusively of these characteristics. It is certain that all unidirectional surge voltages of highest crest value are not of negative polarity, for several of positive polarity have been recorded. High-voltage surges of negative characteristics are in the majority however.

The oscillatory surges have been classified as highly damped *H D*, medium damped *M D*, and slightly damped *S D*. The *H D* figures are accepted without question. The *S D* figures are of doubtful origin.

The *M D* figures appeared only on one system, which operates with an isolated neutral. These figures reached a magnitude of 7.7 times normal and are thought to be associated with arcing grounds.

Surge voltages of the following upper magnitudes have been measured on the various systems:

Due to lightning, 7 to 12 times normal.
Due to switching, 2 to 5 times normal.

These values check those of previous investigations.[7]

It has been fairly well established that the voltage is limited by the flashover strength of the line insulators which on the average system is from 10 to 14 times normal[4] (normal equals crest value of line to neutral voltage).

Very little is known yet about the shapes of the waves encountered in lightning and other line disturbances. The wave-front varies through wide limits. Of 154 surges examined, about one-fifth had fronts between one and ten microseconds, about one-fifth between 10 and 100 microseconds, and about three-fifths over 100 microseconds.

An empirical formula has been derived for attenuation. This is of the form $A = k\,e^2$. That is, the attenuation is faster the higher the voltage. The form of this equation is similar to that for corona loss, $p = c\,e^2$, and indicates that the attenuation is due mainly to corona loss.

The study has shown the benefit due to overhead ground wire in some cases to be very small and in other cases to be almost up to the theoretical value. A conclusive study is very difficult to make, as it is almost impossible to obtain two lines of identical arrangement, in identical territory, subject to the same lightning conditions, and one with and one without ground wire.

The data as to the effect of choke coils and lightning arresters are meager and more information must be obtained along this line.

The data showed from 6 to 15 per cent difference of potential across the standard line choke coils.

Lightning arresters showed discharge currents varying from 150 to 2600 amperes.

In the present year efforts are to be made to obtain more complete and exact data on a few systems. A special effort will be made to obtain data on wave-shape, attenuation, effect of ground wires, and effect of lightning arresters and choke coils.

### ACKNOWLEDGMENTS

The laboratory work in connection with this investigation was under the direction of Mr. E. S. Lee.

Acknowledgment is due C. M. Foust, A. L. Price, F. B. Menger, J. A. Tiedeman, R. F. McAtee, and others of the General Engineering Laboratory and J. B. McClure of the Central Station Engineering Department of the General Electric Company for their painstaking work in handling, analyzing, and correlating the large mass of data accumulated in this investigation. The hearty cooperation of the various power companies is also acknowledged.

# Lightning Investigation on New England
## Power Company System

BY E. W. DILLARD[1]
Associate, A. I. E. E.

***Synopsis.**—An analysis of the surges recorded during 1927 on a 75-mi. 110-kv. double-circuit transmission line of the New England Power System is presented in this paper. The surges are classified according to cause of surge-voltage damping, extent, etc. General conclusions are drawn regarding the nature of surges and protection afforded by ground wires.*

### INTRODUCTION

In long overhead transmission systems lightning disturbances constitute the greatest hazard to service. Perfect relay operation, even if it could be maintained, does not accomplish a complete cure, for usually system surges cause difficulties to a large number of users. Increasing standards of service emphasize the necessity of studies of lightning phenomena.

In making such studies on the New England Power System, we have considered that three general classes of information should be obtained.

FIG. 1—PART OF NEW ENGLAND SYSTEM SHOWING HARRIMAN-MILLBURY LINE

1. Magnitude, extent, and character of lightning disturbances.
2. Protection afforded by ground wires.
3. Relative magnitude of surges of other than lightning origin.

### DESCRIPTION OF LINE

In an effort to get information of this nature records have been made of the surges occurring on the 110-kv. line of this company extending from Harriman, Vermont, to Millbury, Mass., a distance of 74.6 mi. A map of part of the system showing the Harriman-Millbury line is given in Fig. 1.

This line was chosen for investigation because of its unusual construction features. The general type of construction is shown by Fig. 2. Horizontal arrangement was used to give better performance under sleet conditions, lessen the chances of arcs blowing from phase to phase, and to give a lower height of conductors above ground. A ground wire was installed over one circuit only. The characteristics of the line are:

| | |
|---|---|
| Circuits | Two three-phase |
| Length | 74.6 mi. |
| Operating voltage | 110 kv. |
| Frequency | 60 cycles |
| Insulator—suspension | 8 disks |
| Insulators—strain | 9 disks |
| Conductors | 4/0 copper |
| Ground wires | One 7/16-in. crucible steel |
| Transpositions | Nine (three complete rolls) |
| Conductor spacing | 12 and 13 ft. |
| Average height of conductors above ground (entire line) | 42.15 ft. |
| Maximum elevation above sea level | 2100 ft. |

### SURGE-VOLTAGE RECORDER INSTALLATION

Through cooperation with the General Electric Company, surge-voltage recorders were installed and operated during the summers of 1926 and 1927. There was very little lightning in 1926 after the recorders were installed. During 1927 unusually severe lightning conditions were experienced and only 1927 surge-voltage records are discussed in this paper. Surge-voltage

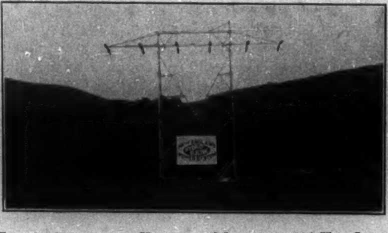

FIG. 2—TOWER ON HARRIMAN-MILLBURY 110-KV. LINE

records are supplemented by operating data of this and other years.

---

[1] Electrical Engineer, New England Power Company.

*Presented at the Summer Convention of the A. I. E. E., Denver, Colo., June 25-29, 1928.*

A total of twenty surge recorders was installed. Fig. 3 shows the location of the instruments. Three were installed on the north line at Harriman, six at the first intermediate station, two at the second intermediate station, six at the third intermediate station, and three on the south line at the Millbury station. Fig. 4 is a photograph of the installation at an intermediate station. Fig. 5 shows a typical record obtained.

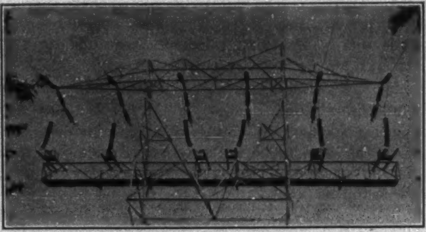

FIG. 4—SURGE-VOLTAGE RECORDER INSTALLATION

## RESULTS

A total of 155 surge voltages was recorded between June 6, 1927, and October 10, 1927. These may be classified according to origin and maximum recorded voltage as follows:

| | | |
|---|---|---|
| Lightning | 104 | maximum 900 kv. |
| Switching | 29 | maximum 360 kv. |
| Unknown | 22 | maximum 270 kv. |

Fig. 6 shows the number of surges recorded at various voltages. Only about 20 per cent of the recorded lightning surges were above 450 kv. No surge-voltage recorder indicated a high enough voltage to cause an insulator flashover, but during this period 47 trip-outs were experienced on the line. It is believed this observation indicates high decrement of lightning voltages rather than any inaccuracy of measurement.

Fig. 7 shows the number of surges at various voltages segregated according to amount of damping. The 104 lightning surges can be classified according to nature as follows:

| | | |
|---|---|---|
| Highly damped | 71, | Maximum 900 kv. |
| Slightly damped | 19, | Maximum 670 kv. |
| Highly damped and slightly damped, mixed | 14, | Maximum 900 kv. |

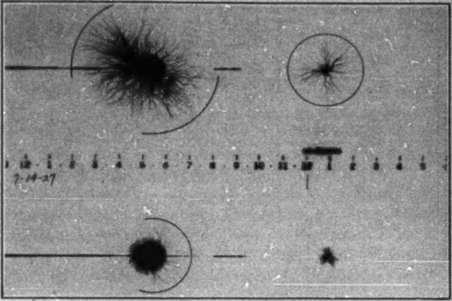

FIG. 5—SURGE-VOLTAGE RECORDER FIELD RECORD

At left, large highly-damped figure from lightning, small slightly-damped figure superimposed. At right small highly damped figure from lightning.

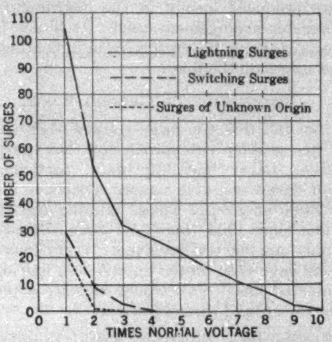

FIG. 6—NUMBER OF SURGES OF DIFFERENT ORIGINS WHICH EXCEED VARIOUS TIMES NORMAL VOLTAGE VALUES

| Cause of surge | No. highly damped | No. slightly damped | No. highly damped and slightly damped |
|---|---|---|---|
| Lightning | 71 | 19 | 14 |
| Switching | 27 | | 2 |
| Unknown | 10 | 12 | |

These results indicate a preponderance of highly damped surges both in regard to magnitude and to number. The inference to be drawn from this fact is that the surges most likely to cause flashovers are unidirectional. The origin of the slightly damped surges is not definitely known. There are indications that they are produced locally in the instrument by the potentiometer arrangement used. It is not felt that these records should be interpreted as indicating slightly damped surges on the line.

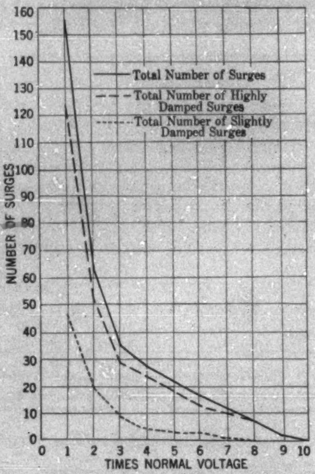

Fig. 7—Number of Surges at Various Times Normal Voltage

### Protection of Ground Wire

It is not felt that the surge-voltage-recorder data in regard to ground-wire protection are particularly conclusive. Other operating data, particularly the record of flashovers, give a more conclusive indication of the value of ground wires. During the operation of the line, since 1924, there have been 57 flashovers in which only one line was involved. Forty-four of these flashovers have been on the unprotected line and 13 on the protected line. This would indicate a protective ratio for the ground wire of 3.4 to 1.

It is probable that the surge-recorder tests would have been more conclusive on this point if they had been more comprehensive. The information obtained in these tests is also confused by the fact that the lines are transposed.

Data from one of the intermediate stations, Barre, at which recorders were installed on all six conductors are shown in the following table. In order to eliminate the effect of transposition as much as possible, only those surges having their highest voltage at Barre are included as these surges probably originated near Barre and therefore their records were least affected by transposition. The ground wire at this point is above and between conductors 2 and 3.

Surge Voltages Having Their Highest Value at Barre
Ground Wire is Above Conductors 2 and 3.

| Surge No. | 1 | 2 | 3 | 4 | 5 | 6 |
|---|---|---|---|---|---|---|
| | | | Times Normal Voltage | | | |
| 59 | 5.2 | 3.9 | 3.3 | 2.2 | 4.2 | 4.2 |
| 66 | 9.0 | 3.9 | 6.5 | 3.8 | 6.0 | 6.1 |
| 88 | 3.1 | 2.5 | 4.0 | 2.8 | 3.5 | 5.3 |
| 113 | 2.8 | 2.7 | 3.2 | 2.8 | 2.7 | 8.3 |
| 114 | 4.0 | 2.8 | 3.9 | 5.0 | 5.5 | 8.3 |
| Average | 4.8 | 3.1 | 4.2 | 3.3 | 4.4 | 6.4 |

It is seen that no definite conclusions as to the value of the ground wire can be drawn from these results.

### Conclusions

1. On this system during the period of the investigations practically all surge voltages of appreciable magnitude due to lightning were unidirectional or highly damped and of negative polarity.

2. No switching surge of greater than four times normal was found.

3. The maximum voltage of a lightning disturbance does not seem to be impressed over more than a very limited portion of the line. More study should be given to this point.

4. The data collected by the surge-voltage recorder do not allow definite conclusions to be drawn relative to ground-wire protection. Other data from operating records indicate worth-while protection.

## Discussion

For discussion of this paper see page 1147.

# Surge-Voltage Investigations on the 140-Kv. System of the Consumers Power Company During 1927

BY J. G. HEMSTREET*
Associate, A. I. E. E.
and
J. R. EATON*
Associate, A. I. E. E.

***Synopsis.**—During the past four years, the Consumers Power Company has been making studies of surge voltages on its 140-kv. system in Michigan. Previous Institute papers have summarized the results of these investigations up to the end of 1926. This paper describes the system, outlines the studies made during the summer of 1927, and presents the results obtained during that season.*

### INTRODUCTION

IN an effort to learn more of the electrical behavior of transmission lines, particularly under transient conditions, the Consumers Power Company and the General Electric Company conducted a cooperative investigation on the Power Company's 140-kv. transmission lines during the summer of 1927. Surge voltage recorders were connected to the lines at various points in order to measure the magnitude and time of occurrence of transient voltages. Data obtained from these instruments were correlated with system operation and disturbances as recorded in the load despatchers log.

FIG. 1—CONSUMERS POWER CO., 140-KV. TRANSMISSION SYSTEM 1927

□ Oil circuit breakers
X Surge-voltage recorder stations

### DESCRIPTION OF SYSTEM

The 140-kv. interconnected system of the Consumers Power Company is shown diagramatically on the map of the State of Michigan, Fig. 1. The system consists of three distinct parts interconnected through frequency changers and transformer banks:

1. The 140-kv., 30-cycle lines on the western side of the state from Hodenpyl Dam through Grand Rapids to Kalamazoo and Battle Creek. (Known as T-20)

2. The 140-kv., 60-cycle lines from Kalamazoo through Battle Creek to Jackson. (Known as J-10)

3. The 140-kv., 60-cycle lines from Mio and Edenville through Saginaw and Flint to Battle Creek. (Known as H-8, K-11, and Edenville)

The 140-kv. system is operated with isolated neutral throughout. Numerous spur lines of lower voltages feed from the various stations on the 140-kv. system.

### TRANSMISSION LINES ON WHICH INSTRUMENTS WERE INSTALLED

The surge-voltage investigation was conducted on the H-8 and K-11 lines between Saginaw River Steam Plant and Flint. Under normal conditions, these two lines operate in parallel, being tied together at the substation buses. The design characteristics of these lines are shown in Table I. At the beginning of the summer neither line was equipped with a ground wire, but during the summer a ground wire was strung in place over the K-11 line. As these two lines are relatively close together, they are subjected to about the same storm conditions.

Eighteen surge-voltage recorders were installed on the lines as shown by the diagram of Fig. 4. On each line, instruments were connected to all three phases at two towers, one of which was 2½ mi. from the Saginaw River Steam Plant and the other about 3½ mi. from Flint.

*Ground wire on K-11 line strung in position between June 12 and August 14, 1927.

Two additional recorders divided the intervening line into three approximately equal parts. At the tower nearest Flint on the K-11 line and in the middle of the adjoining span, surge recorders were installed to measure any voltage which might appear between the ground wire and the ground. Typical installations are shown in Figs. 5, 6, and 7.

## SURGE-VOLTAGE RECORDERS

The surge-voltage recorder used in the investigation was a two-electrode instrument which measured all transients by positive Lichtenberg figures.[3] Connection to the line was made through a capacitance potentiometer consisting of a string of 15 standard suspension insulators, one end of which was connected to the line and the other end grounded. Instrument potential was obtained by a connection to the cap of the second insulator from the grounded end of the string. The recorders on the ground wire were directly connected, giving the same voltage on the instrument terminals as was built up on the ground wire.

## DURATION OF THE INVESTIGATION

All surge-voltage recorders on the line conductors were put in service on May 31 and June 1, and those on the ground wire, on July 8, 1927.

On September 14, two instruments were stopped,

---

1. For references see bibliography.

and on September 20 and 21, the remaining recorders were taken out of service.

### RESULTS

During the period of the investigation, 219 surge voltages, classified as to origin as given in Table II, were recorded.

### SURGE VOLTAGES DUE TO LIGHTNING

*Number and Magnitude.* During the investigation, 76 surge voltages, which were attributed to lightning, were recorded. The number of these surges, exceeding various times normal values, is shown by the curves of Fig. 8. It will be noted that only 20 per cent of the recorded voltages exceeded five times normal. (570 kv.)

*Polarity.* Surges voltages attributed to lightning are classified as to polarity in Table III.

These data indicate that all lightning surge voltages of appreciable magnitude on this particular system were oscillatory during the period of the tests. This statement cannot be made as a definite conclusion because of several factors among which are:

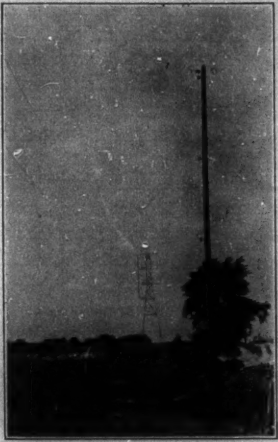

FIG. 7—SURGE RECORDER INSTALLATION AT MID-SPAN OF GROUND WIRE
K-11 line

TABLE II
CLASSIFICATION OF SURGE VOLTAGES

| Origin | Number | Highest crest value | |
|---|---|---|---|
| | | Times normal | Kv. |
| Lightning | 76 | 10.0 + | 1140 |
| Switching | 93 | 3.3 | 375 |
| Accidental short circuits and grounds | 1 | 3.6 | 410 |
| Unknown | 49 | 5.7 | 640 |
| Total | 219 | | |

Note: Normal crest voltage to ground = 114 kv.

1. The possibility of reflections with reversed polarity of voltage.

2. Possibility of secondary oscillatory surges resulting from circuit-breaker operation.

3. Because of limitations of the instrument, two unidirectional surges of opposite polarity, occurring

with little intervening time interval, record as one oscillatory surge voltage.

*Nature.* Lichtenberg figures of three different natures were recorded by lightning surge voltages: highly damped (H. D.), medium damped (M. D.), and slightly damped (S. D.). The highly damped figures are interpreted as having been produced by surge voltages which were of extremely short duration, lasting for only a few polarity reversals. The medium damped figures are produced by surge voltages which are less rapidly damped and may last for an appreciable length of time. Such surge-voltage registrations in almost every case correlated with arc-over from line conductor to ground and with automatic circuit breaker operation. These medium damped figures apparently are peculiar to the isolated neutral system, and are probably produced by line oscillations following flashover. The slightly damped figures are of uncertain origin and seem to be dependent upon the type of potentiometer with which the surge recorder is connected to the line. In view of this uncertainty, conclusions drawn from slightly damped figures are open to question. Continued laboratory studies should lead to an accurate interpretation of the slightly damped figures. The number and magnitude of lightning surge voltages under the above classification are shown in Table IV.

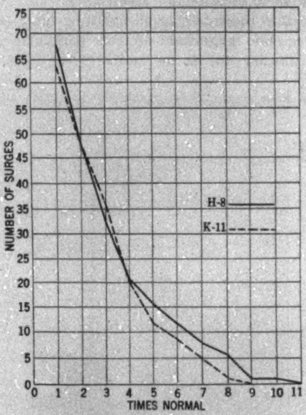

Fig. 8—Number of Lightning Surge Voltages Exceeding Various Times-Normal Values

TABLE III
POLARITY OF LIGHTNING SURGE VOLTAGES

| Polarity | Number | Highest crest value | |
|---|---|---|---|
| | | Time normal | Kv. |
| Unidirectional | | | |
| Positive | 1 | 1.9 | 216 |
| Negative | 3 | 1.2 | 137 |
| Oscillatory | | | |
| Highest crest value | | | |
| Positive | 28 | 8.4 | 960 |
| Negative | 20 | 7.5 | 855 |
| Positive and negative crest values equal | 24 | 10.0 + | 1140 + |

TABLE IV
NATURE OF LIGHTNING SURGE VOLTAGES

| Nature | Number | Highest crest value | |
|---|---|---|---|
| | | Time normal | Kv. |
| H. D. | 13 | 7.5 | 855 |
| M. D. | 10 | 7.7 | 877 |
| S. D. | 16 | 7.8 | 890 |
| H. D. M. D. mixed | 12 | 7.1 | 810 |
| H. D. S. D. mixed | 7 | 7.3 | 832 |
| M. D. S. D. mixed | 11 | 8.8 | 1000 |
| H. D. M. D. S. D. mixed | 7 | 10.0 + | 1140 + |
| Total | 76 | | |

Surge voltages which were recorded by highly damped or slightly damped figures were very similar as regards magnitude and extent over the transmission system. In almost all cases such disturbances were confined to less than 20 mi. of line. The magnitude of surge voltages recorded by medium damped figures was slightly less than the magnitude of those producing highly damped or slightly damped figures, but they were quite different in that they recorded with almost equal value at all instrument locations.

*Attenuation Along the Line.* As pointed out above, surge voltages of medium damped characteristics are recorded with almost equal magnitudes at all recorder stations, and hence show practically no attenuation along the line. Surge voltages recorded by either slightly damped or highly damped figures showed considerable reduction in magnitude from one instrument station to the next. Surge voltages of the highly damped type in some cases reduced from 250 kv. to 0 kv. in 10 mi., or at the average rate of 25 kv. per mile. Those recorded by slightly damped figures, in some cases reduced from 900 kv. to 300 kv. in 10 miles, or at an average rate of 60 kv. per mile.

Comparison of insulator flashover to surge voltage recorder data showed that in some cases the voltage reduced from a value sufficient to cause insulator flashover (about 1000 kv.) to 500 kv. in distances of 4 to 10 miles. This indicates average reductions in voltage between 50 and 125 kv. per mile.

*Protective Value of the Ground Wire.* During the investigation, a ground wire was strung in place over the K-11 line, making possible a study of the operation of this line with and without a ground wire, and a comparison of its performance to that of the H-8 line which has no ground wire. Fig. 9

shows the number and magnitude of surge voltages recorded on the H-8 and K-11 lines before the ground wire was completely installed on the K-11. These curves indicate that during that period, the voltages recorded were about equally severe on the two lines. The curves of Fig. 10 show the number and magnitude of the surge voltages recorded after the ground wire was installed. It will be noted that during this period, the recorded surge voltages were considerably less severe on the K-11 than on the H-8.

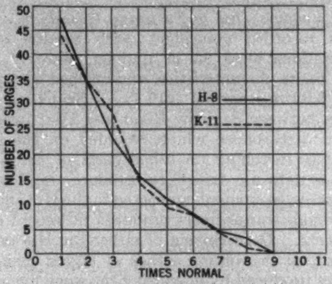

Fig. 9—Number of Lightning Surge Voltages Exceeding Various Times-Normal Values

Before ground wire was installed on K-11 line

*Relation of Conductor Height to Voltage Measured.* The curves of Fig. 11 and 12 show the magnitude and number of surge voltages recorded on the top, middle, and low conductors of the H-8 and K-11 lines, respectively, using only the data obtained at those stations where instruments were installed on all three conductors. From these curves, it is seen that no definite relation exists between the magnitude of surge voltages measured and conductor height. It is thought that transpositions in the line, reflection of the transient waves, and other factors, so complicate this study that voltages measured at a few recorder stations do not give a true indication of the relative voltages induced at the origin of the lightning disturbances.

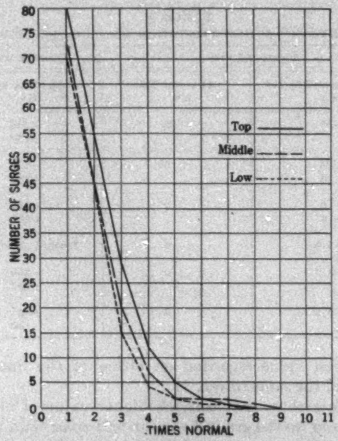

Fig. 12—Number of Lightning Surge Voltages Exceeding Various Times-Normal Values, Recorded on Top, Middle, and Low Conductors

K-11 line

*Surges Coincident with Switch Trip-Out.* In every case of switch trip-out on the 140-kv. system, surge voltages were recorded at one or more of the surge recorder stations. Trip-outs of the H-8 or K-11 lines between Saginaw River and Flint produced registrations on practically all instruments in operation. In some instances, the recorded voltages were low (400 kv.) as compared with the generally accepted value of insulator flashover (approximately 1000 kv.). However, it is reasonably certain that in such cases, the lightning discharge took place at a point on the line some distance from a recorder station, and the voltage wave attenuated considerably before reaching the first instrument. The transient recorded at the various instrument stations was probably the result of the arcing ground or of circuit breaker operation, rather than of the voltage disturbance set up by the lightning itself. The figures recorded at the time of switch trip-outs were predominately of the nature designated as medium damped, although also highly damped and slightly damped figures were frequently recorded.

Surge voltages not coincident with switch trip-outs were for the most part very local in extent, of values from 1 to 10 times normal (114 to 1140 kv.) and of all three figures types with those of highly damped and slightly damped characteristics predominating.

*Surge Voltages on the Ground Wire.* Table V shows the lightning surge voltages recorded on the ground wire at mid-span and at the tower, and the highest value recorded on either of the line conductors at the same tower.

TABLE V
LIGHTNING SURGE VOLTAGES ON GROUND WIRE

| On ground wire | | On conductor |
|---|---|---|
| At mid-span 318-319 Kv. | At tower 318 Kv. | At tower 318 Kv. |
| +35+ | +28 | +206<br>−160 |
| +24<br>−16 | 0 | −456<br>+285 |
| − 6<br>+ 4 | 0 | −410<br>+285 |
| +5.5 | 0 | Record obscured |
| −3.7 | 0 | −850<br>+182 |
| +2.0 | 0 | +205<br>−160 |

The data show that a much higher value of voltage may appear on the ground wire at mid-span than at the tower, possibly due to the finite length of time required for the transient to travel along the wire to ground at the tower.

*Line Failures.* During the operation of the surge recorders lightning caused failure of the H-8 line about 50 mi. southwest of Flint when an insulator flashover burned off one of the conductors, permitting it to short-circuit with the conductor below and to fall to the ground. Automatic circuit-breaker operation cleared the section of line in trouble. The disturbance produced a registration on all but two of the instruments on the line conductors. In general, the surge recorded was of moderate value, but on $Y$-phase, tower 1692 of the H-8 line it reached a value of 7.7 times normal (880-kv.).

*Surge Voltages Due to Switching Operations.* Surge voltages recorded coincident with routine switching operations were 92 in number, were of highly damped figure characteristics, and reached a maximum value of 3.6 times normal (410 kv.). Switching on the two lines between Saginaw River and Flint invariably produced disturbance which recorded on the instruments, but switching on other parts of the 140-kv. system sometimes failed to produce registrations. Switching on equipment connected to the H-8 and K-11 lines through transformers produced no record on the instruments. Deenergizing of either the H-8 or K-11 lines resulted in voltage surges of higher magnitude than were produced by energizing the same line.

*Surge Voltages from Unknown Causes.* During the season, 49 surge voltages were recorded for which no cause could be assigned. These voltage disturbances were all oscillatory and, for the most part, very local in extent. They were of relatively small magnitude, the majority being less than 3.0 times normal (340 kv.), and the most severe 5.7 times normal (650 kv.). Surge voltages of highly damped, medium damped, and slightly damped characteristics were about equal in number.

It is thought that these surge voltages for which no cause could be assigned may have been produced by switching operations not listed in the load despatchers log, or by local lightning storm which were not noted by the operators.

## SUMMARY OF RESULTS

On the 140-kv. lines of the Consumers Power Company between Saginaw River and Flint in 1927:

1. Lightning produced voltage surges whose magnitudes were as high as 1100 kv.
2. During this particular investigation, all surge voltages of appreciable magnitude due to lightning recorded on the two-electrode instrument as oscillatory, with no preponderance of positive or negative polarity indicated. In a number of cases, the record of the surge from the lightning itself was undoubtedly considerably obscured by secondary oscillations from arcing grounds and circuit breaker operation.
3. The surge voltages due to lightning were characterized by three different figure types; highly damped, medium damped, and slightly damped.
4. Surge voltages characterized by medium damped figures showed very little change in value from station to station, and frequently correlated with arcing grounds and switch trip-outs.

5. Comparison of simultaneous registrations of highly damped and slightly damped surge voltages showed the reduction in voltage from station to station to be of the order of 50-kv. per mi. From insulator flashover, the attenuation appeared to be in the order of 100 kv. per mile.

6. The data indicated that the ground wire afforded some protection against lightning disturbances.

7. No definite relation was shown between conductor height and voltage recorded.

8. Surge voltages recorded coincident with switch trip-outs due to lightning frequently were of a magnitude less than 400 kv., though higher voltages undoubtedly existed on the line at points remote from recorder stations.

9. Lightning surges which produced no switch trip-outs were, as a rule, very limited in their extent although they were frequently of a very high value. (800-1100 kv.).

10. Under lightning conditions, voltages in excess of 35 kv. were built up between ground wire and ground at mid-span, without excessively high voltage on the line conductors. The voltage from ground wire to ground was always considerably less at the tower than at mid-span.

11. Normal switching operations produced surge voltages of low value which extended over considerable length of line.

12. Numerous surge voltages were recorded which could not be correlated with lightning storms or system switching. The magnitudes of such disturbances were relatively low, reaching values no higher than 5.7 times normal (650 kv.).

# Surge Voltage Investigation on the 132-Kv. Transmission Lines of the American Gas and Electric Company

BY PHILIP SPORN[1]

Member, A. I. E. E.

*Synopsis.—Data on the surge voltage investigation, carried out under the auspices of the Subcommittee on Lightning, on one of the 132-kv. lines of the American Gas and Electric Company during 1928, are presented. Most of the surges have been segregated as to cause, and plotted in summary form for more convenient use. The magnitude and character of recorded surges are discussed; and the conclusions drawn from data presented.*

*Information on voltage surges due to lightning, switching, trip-outs, and unknown causes are presented, as well as records of lightning arrester discharge currents, voltages across choke coils, and on the ground wire.*

*This paper is presented at this time to make available to the engineering profession some of the information obtained, before the report of the Subcommittee on Lightning is completed. As experimental work is still being done in the field during 1928, anything like a complete report cannot be made until next year.*

## I. INTRODUCTION

IN carrying out the work of the Subcommittee on Lightning of the Transmission and Distribution Committee of the A. I. E. E. with the author as Secretary, an extensive klydonograph layout was planned and placed in operation on the 132-kv. system of the American Gas and Electric Company during the lightning season of 1927. This work, started under the sponsorship of the Subcommittee on Lightning, was made possible by the cooperation of the General Electric Company, the Westinghouse Electric and Manufacturing Company, and the American Gas and Electric Company, and the subsidiaries of the latter, namely, the Ohio Power Company and the Appalachian Electric Power Company.

This paper presents some of the first data obtained from the investigation on one part of the system. It is planned to combine with all the 1927 work, data from other parts of the system, where the investigation was carried on, together with results secured from the continuation of tests during 1928, and present it later as a complete report by the Lightning Subcommittee.

## II. SYSTEM INVESTIGATED

In selecting a system on which to carry on this work during 1927, the Lightning Committee decided the 132-kv. Philo-Canton line of the American Gas and Electric Company was particularly well suited, as this line had experienced a great deal of lightning trouble when first placed in service.[2] It had been supplied, after careful study, with protective equipment designed to minimize lightning troubles; and it was situated in a section of the country where lightning storms were known to be unusually severe.

The Philo-Canton line is a 73-mi., double-circuit A. C. S. R. conductor line, with wires in vertical configuration, one circuit on each side of the tower. The line is equipped with ring and horn protection on all insulator strings, and with one ground wire at the peak of the tower. This line is in Ohio, parallel to, and about 50 mi. west of the Ohio River. The 123-kv. system is operated with solidly grounded neutral, the only ground on the Philo-Canton line being at the Philo end.

In carrying out the program, tests were made also on a 132-kv. lightning arrester at the Turner substation located in Charleston, West Virginia.

This paper covers only results obtained on the Philo-Canton line and on the lightning arrester at Turner substation.

## III. SCOPE OF INVESTIGATION

In planning the installation of instruments, locations were so chosen that it was expected valuable information would be obtained on the following:

1. Choke coil effectiveness.
2. Ground wire protection.
3. Polarity of lightning.
4. Transient voltages on the ground wire.
5. Functioning of lightning arresters.
6. Attenuation of voltage surges.
7. Voltage change at termination of ground wire.
8. Switching surges.
9. Action of tower ground resistance during insulator flashover.
10. Relative surge voltages on symmetrically placed parallel conductor.

The first instruments were placed in service May 10, 1927, and the major part of the installation completed about June 15. The investigation as a whole was concluded October 16, 1927, although some of the instruments at the stations, where they were accessible, were continued in operation throughout the winter of 1927-1928.

## IV. LOCATION OF INSTRUMENTS

The general location of klydonograph is shown in Fig. 1. The set-up included 37 G. E. double reverse electrode surge recorders and one Westinghouse four-electrode klydonograph. As connected, the instru-

[2] *Lightning and Other Experience with 132-Kv. Steel Tower Transmission Lines,* Sindeband and Sporn, A. I. E. E. TRANS., Vol. 45, 1926, p. 770.

*Presented at the Summer Convention of the A. I. E. E., Denver, Colo., June 25-29, 1928.*

ments were capable of recording surges at 40 different points on the system. It was realized, of course, that while instruments were located with a definite object in view, they would obviously record any and all surges on the line and therefore, information other than that specifically planned for would be obtained.

In analyzing the layout, reference to Fig. 1 shows that stations Nos. 1 and 5, also 32 and 33, were located to determine the voltage change across choke coils. Ground wire protection data were expected from instruments 7 to 19, 21 to 23, 33, 34, and 35. From the instruments located at Stations 7 to 19, inclusive, it was expected that some information would be obtained on the attenuation of surges. Data on voltage characteristics at the termination of ground wire were expected at Stations 5, 41, 7, 29, and 32. A lightning arrester study was undertaken by instruments at Stations 4, 5, 24, 30, 31, and 38. At Station 42 an instrument was connected to the ground wire at the peak of the tower to measure the voltage on the ground wire. At Station 43, an instrument was connected from the base of the tower to an artificial ground system made from ground rods located at least 10 ft. from the base of the tower. This set-up was made to determine, if possible, any voltage change between the tower base and normal ground due to any drop through the tower ground resistance in case of flashover at this tower. Another interesting set-up is at Tower 172 including Stations 20, 21, 22, and 23. This set-up was made to compare the two different types of instruments used and their couplings to the line. Station 20 is a three-electrode Westinghouse klydonograph coupled to the line with pipe type potentiometers and Stations 21, 22, and 23 are equipped with G. E. surge-voltage recorders coupled to the line with insulator string potentiometers.

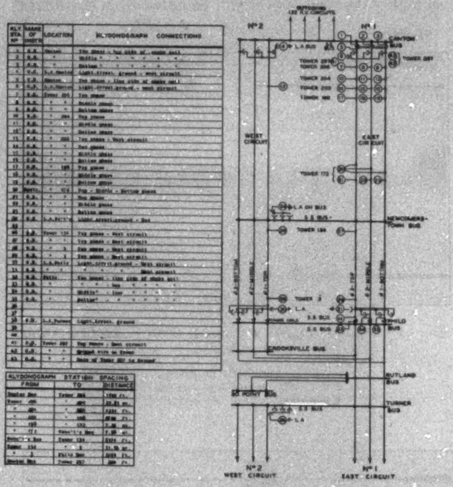

FIG. 1—KLYDONOGRAPH LAYOUT—132-KV. SYSTEM 1927 TESTS

Two typical set-ups of the instruments in the field at Stations 20, 21, 22, and 23 are shown in Figs. 7 and 8. Figs. 7 and 8 show the tap leads extending from the line to the klydonograph stations located at the base of the tower, both pipe type and insulator string potentiometers with klydonographs appearing clearly in the foreground.

The insulator string potentiometer connections at Stations 1, 2, 3, and 5 are shown in Fig. 9. The klydonograph is shown tapped across the lower insulator of the entire string. In the first part of the test the instrument was tapped across the two lower units, but this connection was later changed so as to tap one unit, thereby increasing the potentiometer ratio.

## V. POTENTIOMETER COUPLING TO 132-KV. CIRCUITS

The klydonograph and surge voltage recorder, the action of which is well known, has been described previously.[3] Since these instruments are suitable for connecting to a circuit, the crest voltage of which under surge conditions ranges from 1500 to 30,000 volts,[4]

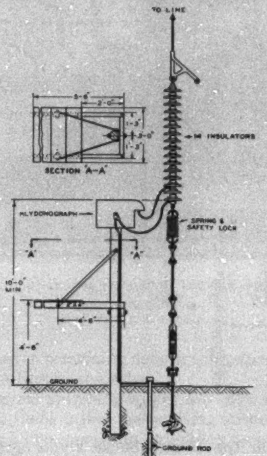

FIG. 2

---

[3] *The Klydonograph and Its Application to Surge Investigation*, Cox and Legg, A. I. E. E. TRANS., Vol. 44, 1925, p. 857.

*The Measurement of Surge Voltages on Transmission Lines due to Lightning*, Lee and Foust, A. I. E. E. TRANS., Vol. 46, 1927, p. 339.

[4] The klydonograph will not record crest voltages below 1500, and flashes over around 30,000.

the instrument must be provided with suitable reduction equipment to connect to high-voltage circuits of the order of 132,000 volts (108,000 volts crest to ground). In these tests two types of potentiometers were used to reduce the normal line voltage to a voltage suitable for the instrument. One type, the insulator string potentiometer, is shown in Fig. 2, and consists essentially of 14 line insulators with the instrument tapped across the lower insulators on the ground end of the string. This type of potentiometer connected to the high voltage side of the circuit, was used with all G. E. surge recorders. The other type potentiometer shown in Fig. 3, was used on the Westinghouse klydonograph. This potentiometer consists essentially of four 3-in. pipes approximately ten feet long assembled with two strings of line type insulators. With the insulator string potentiometer a ratio of approximately 52/1 was secured when tapping the bottom insulator and 38/1 when tapping the bottom two insulators. The ratio used with the pipe type potentiometer was approximately 65/1. There are two main differences in these two types of potentiometers. First, with the insulator type the dielectric field is principally in porcelain, while with the pipe type it is mainly in the air. Second, the klydonograph is tapped across a part of the insulator string leakage path with the insulator string type potentiometer, but this is not the case with the pipe type of potentiometer.

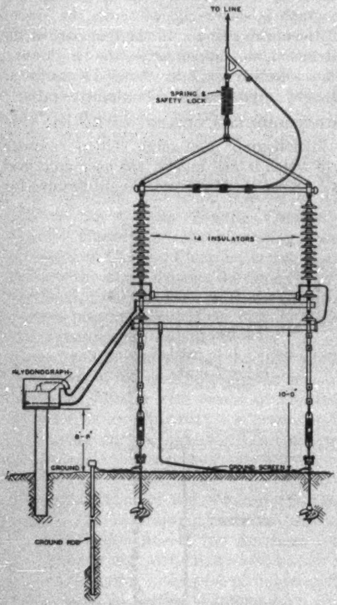

FIG. 3

## VI. CHARACTER OF SURGES

The general types of Lichtenberg figures obtained on all records are shown in Figs. 4, 5, and 6. In Fig. 4, surge 1 is a typical lightning figure, which is described as highly damped, and it will be noted from the figure that there is a large positive and a very small corresponding negative just observable above the normal voltage band (the large figure may be positive or negative, depending upon which electrode originally recorded it). Surges 2 and 4 are typical switching surges of a highly damped nature and indicate a rather high voltage, but with only a few reversals of high magnitude. This is clearly shown by the lack of density in the figures. Surges 3 and 5 are also switching

surges of a lower magnitude with surge No. 3 showing a tendency for a sustained voltage considerably in excess of normal line voltage. A typical slightly damped figure is shown in Fig. 5. In general, this type of picture indicates an oscillatory voltage sustained for a relatively long period of time. Its reproduction in the laboratory has been approximated by normal frequency voltage for a period in the order of a minute. Although it has never been perfectly reproduced in the laboratory, such attempts as have been made seem to indicate it requires an oscillating voltage and also an appreciable element of time.

A number of this type of surge was obtained during the test period, but as their presence could not be explained, and since, as described later, they appeared to be a function of the potentiometer used, they have not been used in presenting data in this paper, except to indicate that they have existed.

Other typical switching surges are shown in Fig. 6, surge No. 1 being a line deenergizing surge and surge No. 2 being a line energizing surge both recorded at the Canton end of the line.

## VII. DATA OBTAINED AND ANALYSIS

During the period of instrument operation up to October 16, 1927, approximately 3600 Lichtenberg figures, resulting from 550 surges, were obtained on the Philo-Canton section of the system. These surges were classified and regrouped so that a detailed study might be made of any particular type of surge. On the Phil-Canton line these surges have been classified according to cause, as follows:

TABLE I

| | Total | Excluding slightly damped |
|---|---|---|
| Unknown origin | 295 | 272 |
| Outside switching | 29 | 26 |
| Pure switching surges | 101 | 101 |
| Lightning surges | 166 | 96 |
| Combined lightning and switching | 6 | 4 |
| Lightning arrester discharges | 40 | 40 |
| Ground wire surges | 68 | 68 |

*Outside and Pure Switching Surges.* For more convenient study, the surge data have been assembled into summary curves, two of which are shown in Fig. 10. The lower curve applies to outside switching surges and shows that of 26 surges the maximum was 1.8 times normal and that 50 per cent of them were over 1.4 times normal. Outside switching surges are classified as surges originating from switching on parts of the system other than where instruments are located. In some cases surges were caused by switching on the secondary side of the transformers connected to the 132-kv. line. This type of surge has also been included in this curve.

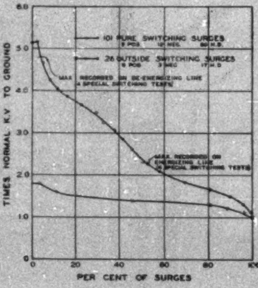

FIG. 10

The upper curve of this Fig. 10 shows the results of 101 pure switching surges with maximum recording value of 5.2 times normal. These surges have been segregated as to nature, showing 9 positive, 12 negative, and 80 highly damped. Two points of the curve have been marked, indicating the maximum recorded voltage on energizing; also on deenergizing the line. These two points were the results obtained on four separate switching tests of the Philo-Canton line, in which surges caused by energizing and deenergizing the line as well as switching load at Newcomerstown (the approximate half way point of the line) were separated by one hour intervals. In the earlier part of the tests it was found that lightning and switching surges occurring at the same time caused some confusion due to the absolute impossibility of separating the switching part of the surge from the lightning part. It was therefore decided to separate the switching surges by one hour intervals in a prearranged test and in this way study the effects of switching load, deenergizing the line, and energizing the line. Results show that the maximum recorded surge occurred on deenergizing the line and was 4.8 times normal. On energizing the line the maximum surge was 2.3 times normal.

To show the effect of the switching voltage throughout the entire length of the line, the records obtained on three of these switching surges are shown in Figs. 12 and 13. The point of interest is that the switching surge travels with apparently little change in the voltage throughout the entire length of the line. The irregularities in the curves are probably within the limits of accuracy in the instruments and the distinct tendency of higher voltages at either end of the line due to reflection will be noted.

Deenergized at Canton station

*Surges of Unknown Origin.* Surges of unknown origin on the Philo-canton line are shown graphically in Fig. 11. While there were 272 surges for which no cause could be found, it will be noted that these never exceeded 2.5 times normal and only five per cent of them exceeded two times normal. This type of surge can be dismissed as being unimportant in magnitude, although constituting a comparatively large number of voltage changes on the line.

*Lightning Surges.* The 96 lightning surges on the Philo-Canton line are summarized in Fig. 14. The maximum surge indicated is 4.4 times normal and 50 per cent of the surges are above one and one-half times normal. These surges have been segregated as to nature predominating in each surge, as follows: 25 negative, 42 positive, and 29 highly damped.

*Lightning and Lightning Surges.* The four lightning surges on the line causing line trip-outs, gave maximum voltages of 5.0 and 3.7 times normal to ground. These were slightly damped surges, and it is believed may have been caused by the switching surge following the lightning voltage flashover. The other two surges recorded a maximum of 5.4 and 6.2 times normal, but both being S. D. figures, the results were not seriously considered. Since lightning voltages over double the values recorded above are necessary to cause insulator flashover, it is clear, even with a fairly large number of instruments on the line, there is no certainty that anything like the maximum voltage on the line will be recorded. As sections of line in the order of 25 mi. existed where no surge recorder was located, this shows that the lightning voltages did not travel with destructive values any great distance. This characteristic of the lightning surge is distinctly different from the switching surge.

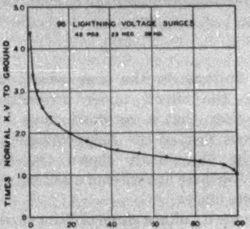

Fig. 14

*Voltage Drop Through Choke Coils.* The attempt to measure the voltage drop through choke coils was rather ineffective on account of the existence of S. D. figures in the records. However, of 10 lightning surges (no S. D. figures included) the bus side of the choke coil was the higher on four surges, averaging nine per cent higher than the line side and on six surges the line side of the choke coil was higher, averaging 25½ per cent higher voltage than on the bus side. It can only be said that a tendency exists, as indicated, for the choke coil to reduce the lightning voltage originating on the line in the order of 25 per cent, but it is not felt that sufficient data on this subject have been obtained to prove finally the effectiveness of the choke coil.

*Lightning Arrester Data.* The data on all six lightning arresters are summarized in Fig. 15. The only record of current discharge in the arresters was obtained at Newcomerstown and Turner substations. No records were obtained at Philo or Canton on lightning arresters due apparently to the arrester not discharging, although the instrument was set up to record a current as low as about 150 amperes in the neutral leg. In Fig. 15 it should be noted that the current and voltage are not simultaneous readings. Forty lightning arrester discharges were recorded; 21 were positive, 11 were negative, and 8 were highly damped. Of the lightning discharges 12 were positive, eight negative, and four highly damped. Of the switching discharges one was positive and one negative. Of the discharges due to unknown causes nine were positive, two negative, and two highly damped. One discharge due to an arcing ground registered minus 360 and plus 410 amperes, being of a highly damped nature. An attempt to plot a curve of current against voltage recorded resulted in a shotgun curve of little value. It is felt that considerably more work will have to be done in securing lightning arrester data before any definite conclusion is arrived at.

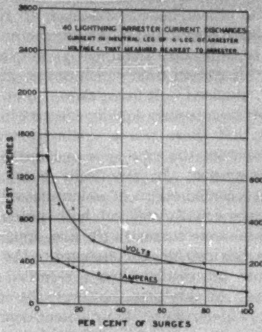

Fig. 15

*Lightning Surges on Parallel Circuits.* The data secured at instruments located on the top wires of the two Philo-Canton lines (eliminating S. D. figures) gave nine surges including four positive, two negative, and three highly damped. The ratio of the two lines at any point varied from 0.80 to 1.25, averaging 1.03. The minimum voltages occurring during these surges were in the order of 120 kv. to 140 kv. minimum to a maximum of 340 to 400 kv. The data here, again, are too meager to prove definitely that the induced voltages on the two wires are equal; but this tendency is indicated.

*Tower Base Voltages.* At Station 43 where an instrument was located to determine the voltage between the tower base and ground, no records were obtained during the season. It should also be noted that at this tower there were no flashovers of the line.

*Comparison of Potentiometer Couplings at Tower 172.* This location of instruments was made to give a comparison of instruments and of potentiometer couplings. Some 300 records were obtained on the instruments located at this station from which certain and definite data were obtained. It was shown that the two types of instruments were equally effective in recording surges, but that there was a distinctly troublesome difference between the pipe type and insulator string type potentiometer. In practically every case the instruments recorded surges of unidirectional or highly damped surges equally well on both potentiometers, but when there were surges on the line, apparently due to lightning, the instrument connected to the pipe type potentiometer practically always recorded unidirectional surges. At this time, however, the instrument connected to the insulator string potentiometer would frequently record surges of a slightly damped nature. That this occurrence was due to the potentiometer alone was definitely proved by coupling two separate instruments to the same point on the line, one through a pipe type and the other through an insulator string type potentiometer. Slightly damped surges, six and one-half times normal and above, were recorded at this station through the insulator string potentiometer which failed to indicate at all through the pipe type coupling. Slightly damped figures as low as 1.8 times normal have been recorded through the insulator string potentiometer which failed to give any record at all through the pipe type coupling.

A study of results secured at this tower led to the conclusion that all of the so-called slightly damped surges recorded in the investigation should be excluded from analysis and consideration, in a study of the data; and this practise has been followed in this report.

Study made subsequently in the laboratory confirmed the impression that the S. D. figures are brought about in some way by a condition in the circuit of the insulator string type potentiometer, and that while a surge occurrence on the line may set off the circuit that finally produces the S. D. figures, that no potential of the order generally indicated by the S. D. figures actually exists on the line itself. All the laboratory work failed to disclose a means whereby an S. D. figure could be actually reproduced. As a consequence, the conclusion was reached to disregard the S. D. figures obtained on the insulator string potentiometer on past work, and in future work to adhere either to the pipe type potentiometer or to a modification of the string potentiometer that would definitely preclude the possibility of the S. D. figure recurring. It appears that if the circuit is so arranged that the instrument itself is not shunted across the 60-cycle leakage path, the S. D. figure will not show up; and work is being done in several directions to effect this change in the potentiometer coupling. From this standpoint it is felt that the layout at Station 172 was a particularly fortunate one, and contributed considerably to the study of lightning phenomena by means of the klydonograph. It has resulted in definitely disclosing a weakness in one type of potentiometer arrangement and has eliminated the possibility of misleading conclusions as a result of faulty data.

*Effect of Normal Line Potential on Recorded Voltages.* The surge recorder shows the maximum crest voltage at its terminals, and by the use of the potentiometer ratio, the crest voltage on the line, when potentiometer coupled to the circuit under investigation. It is, therefore, clear that a recorded surge must be the instantaneous sum of the surge voltage and the line voltage. In Fig. 16 are shown the instantaneous voltages of the three line wires of a 132-kv. circuit during one complete cycle.

Fig. 16—Instantaneous Voltage of 132-Kv., Three-Phase Line

Now assume a voltage surge of 300 kv. positive on all three line wires, and further, that this surge occurs at 210 deg. on the time scale. Due to normal line voltage No. 2 phase is 108 kv. above ground, and No. 1 and No. 3 phases 54 kv. below ground. Surge recorders at this location would indicate the sum of normal plus surge voltage; and conditions in Table II would obtain.

While 18 per cent error in surge recorder instruments, including line coupling in their present stage of develop-

TABLE II

| | Phase 1 | Phase 2 | Phase 3 |
|---|---|---|---|
| Surge voltage (kv.) | 300 | 300 | 300 |
| Line voltage (kv.) | 100 | −54 | −54 |
| Recorded voltage (kv.) | 400 | 246 | 246 |
| Per cent error | 33 | 18 | 18 |

ment, is perfectly reasonable, and 33 per cent may be slightly excessive, let us examine the ratio of recorded to actual voltages on phases 1 and 2. This ratio is 1.63 for the recorded voltage and 1.00 for the actual voltage, giving an error of 63 per cent, which is distinctly excessive if the data are to be used in studying surge voltage attenuation, effect of the ground wire, voltages on lightning arresters and the like.

It should be pointed out, however, that the effect of normal line voltage on surges decreases with increase of the surge magnitude. An error of 63 per cent with a 300-kv. superimposed surge becomes only 18 per cent for a 900-kv. surge. With surges of low magnitude the error becomes greater; and in some cases an erroneous conclusion may be reached unless the influence of normal line voltage is considered.

While the above feature is decidedly fundamental, it is felt that its importance in analyzing data should be emphasized at this time to forestall any wrong conclusions being drawn from data, particularly where surges of the lower magnitudes are involved.

## VIII. CONCLUSIONS

1. The choke coils reduced the recorded lightning voltage in the order of 25 per cent, although tests on this feature are not extensive enough to prove this statement conclusively. Reflections at the choke coil may also have had a decided effect in altering the incoming voltage wave, so that this 25 per cent may not have been an actual reduction of the initial wave.

2. The protective value of the ground wire could not be proved conclusively from the data, due largely to the presence of S. D. figures in the records. It is planned to continue this investigation the coming year.

3. The record on instruments at the time of line trip-outs due to lightning (maximum 5.0 times normal voltage is found) indicates that the voltages higher than recorded must have existed on the line for flashover to have occurred. This brings up the point that surge recorders must be placed in generous numbers on a line to study line performance thoroughly. A further tendency is indicated from these data, that is, that lightning voltages do not travel a great distance; otherwise there would have been recorded high voltages on some of the surge recorders.

4. The polarity of lightning surges indicated a preponderance of positive impulses. Of 96 surges 42 were positive, 25 negative, and 29 highly damped.

5. Transient voltages on the ground wire at the tower were recorded as high as 8200 volts negative during a lightning storm, and in all cases were of the order of 3000 to 4000 volts. These surges were recorded at times of lightning storms and switching; in some cases no cause could be found. This relatively low voltage on the ground wire compared with the higher voltage on the line is positive evidence of the effectiveness of the ground wire in reducing the impulse voltages on the line itself.

6. Lightning arrester discharges in all cases were of the general order of 200 to 400 amperes, although two cases were recorded as high as 1260 and 2620 amperes. Measured currents were in all cases the sum of the currents in all three legs of the arrester. The highest recorded current was negative; the 1260 ampere value was highly damped, being initially negative.

7. Attenuation of lightning surge voltages failed to give any conclusive results largely on account of the presence of S. D. figures.

8. The attempt to determine voltage changes at the termination of the ground wire was not very successful due largely to insufficient reliable data and the proximity of the test point to the substation where the numerous changes in surge impedance introduced the question of reflected waves.

9. Switching surges have been recorded as high as 5.2 times normal, which seems to be in general agreement with previous results. Over 50 per cent of the switching surges were of the order of two and one-half times normal to ground or higher. By isolating switching surges in four special tests, it was shown that the surge voltage on deenergizing the line was approximately twice as great as on energizing the line. Switching surges are mostly of a highly damped nature, as shown by the data.

10. No voltage was recorded between the base of a tower and ground, during the tests, although the voltage at the peak of the tower to which the ground wire was attached indicated surge voltages up to 8200 volts.

11. The relative lightning voltage on parallel conductors is shown to be equal, although the data are too limited to prove this point definitely.

12. It was shown that the two types of surge recorders are equally reliable from the point of view of measuring surges; but it was also shown that the type of coupling employed to connect the instruments to the line must be carefully studied and selected or erroneous conclusions may result. This point is clearly shown from the experience at Tower 172, Stations 20, 21, 22, and 23.

13. This investigation, it is believed, has resulted in some new information, some confirmatory and some negative. All this information is valuable, although a great deal more data must be obtained to properly solve the lightning problem. With this data, together with the data it is hoped to get during the year 1928 lightning season, it is believed some further light will be thrown on the lightning voltage situation.

Acknowledgment is due to the various men in the organization of the General Electric Company, the Westinghouse Electric Manufacturing Company, the American Gas and Electric Company, the Ohio Power Company, and Appalachian Electric Power Company, who participated and helped in the work of this investigation.

## Discussion

For discussion of this paper see page 1147.

# Surge Voltage Investigation on 220-Kv. System of
## Pennsylvania Power and Light Company

BY NICOLAS N. SMELOFF[1]

Associate. A. I. E. E.

***Synopsis.**—This paper presents the history of the operating experience and surge-voltage recorder data for the years 1926 and 1927, on the first 220-kv. line in the East.*

*The system of the Pennsylvania Power & Light Company is described. Lightning weather data, design characteristics of the 220-kv. line involved, and details of connection and installation of surge-voltage recorders are given.*

*The study shows the magnitude of surge voltages encountered, method of classification, effect of our overhead ground wires, etc., and points out the necessity for comprehensive lightning research, which will permit a systematic solution of transmission problems.*

* * * * *

### GENERAL

THE system of the Pennsylvania Power & Light Company is located in the northeastern part of Pennsylvania. It traverses several mountain ranges, which attain a maximum elevation of 2100 ft. In the anthracite coal fields and in the northern part of the system the terrain is particularly rugged, rocky, and exposed to storms.

Coal mining, cement, metallurgical, slate, textile, furniture, shoe, and other miscellaneous industries provide a field for a desirable, important, and diversified load. In addition to the above, a number of large communities depends entirely upon this system for electrical power. The natural growth of the system and favorable economic conditions permit the establishment of interconnections with practically all neighboring systems.

Power is generated in eight major steam stations. With one exception these stations use small sizes of anthracite—either pulverized or on stokers. In addition, one major hydroelectric station of 40,000-kw. capacity at Wallenpaupack furnishes power during peak load periods. This hydroelectric development, because of its design and method of operation, provides on short notice (90 to 120 sec.) a capacity which assists materially in the economical operation of the steam stations.

The present major network and primary distribution is operated at 66,000 volts. Over 50 per cent of this 66-kv. network is on wood pole lines. Numerous step-down transformer stations are connected directly to the main lines, thus affording readily accessible power to large, as well as comparatively small consumers at the system primary voltage.

This 66-kv. system, at present, is connected at Siegfried with the hydroelectric station at Wallenpaupack by means of a 220-kv. transmission line, which was placed in operation in 1926. Although it was the first line operating at this potential in the East, of far more importance is the fact that it was the first 220-kv. line in lightning infested territory, and for this reason it afforded the first substantial experience with an opportunity for study of the effects of lightning on a line and equipment insulated for 220-kv. operation.

During 1928, additional lines at 220-kv. were placed in operation establishing an interconnection between the systems of the Philadelphia Electric Company and the Pennsylvania Power & Light Company, and consequently tying together the two hydroelectric stations, Conowingo and Wallenpaupack. This connection is shown on the map of Fig. 1. Later these lines will be a part of an extensive 220-kv. network and interconnection between large stations of several systems.

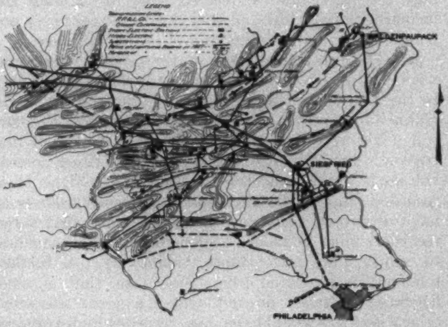

FIG. 1—MAP OF PENNSYLVANIA POWER & LIGHT CO. SYSTEM

Showing major transmission lines, power plants, substations, and the path and number of lightning storms for the season of 1927

### LIGHTNING WEATHER DATA

Lightning weather observations were made by the operating organization at numerous company substations. The data thus obtained were analyzed in conjunction with the U. S. Weather Bureau records.

The map (Fig. 1) indicates the principal mountain ranges and valleys and the paths of lightning storms during 1927. The solid lines denote the main general paths of the storms, while the broken lines indicate divergencies and show how storms break up and follow

---

[1] Assistant to General Superintendent, Pennsylvania Power & Light Co., Allentown, Pa.

*Presented at the Summer Convention of the A. I. E. E., Denver, Colo., June 25-29, 1928.*

different routes. In general, the storms seem to follow the mountain ranges rather closely, breaking through at points where streams have formed definite gaps. The general cyclonic storms moving eastward over the territory, extend from the northern to the southern edges of the system and during the course of their travel are reported from practically all stations. Of approximately 60 storms occurring during the 1927 season, 25 were of this wide-spread type, 26 were of a generally local type, following only one of the various paths indicated, while the remainder were entirely local, being reported from only one or two adjacent stations.

The duration of the storms is variable. The purely local storm may last from fifteen minutes to three hours, depending on conditions at the time it occurs. The general type of storm may be in evidence for a period ranging from two to seven hours before it has entirely disappeared from all parts of the system.

The map (Fig. 1) also shows, for the year 1927, the number of lightning storms reported from various locations. These data are not indicative of storm severity or duration and may or may not represent an average year. From this information it may be seen that the system under discussion is subjected to lightning storms in excess of the average over the country.[2] The records show that during 1927, 35 of the total of 59 storms observed caused line trip-outs, for the year 1926, 40, and for 1925, 51 storms caused trip-outs and were recorded. No complete record was kept of storms which did not affect operation during these earlier years.

Showing locations of surge-voltage recorders, transpositions, protective gaps, and overhead ground wires

## OBJECT OF SURGE VOLTAGE STUDY

The importance of successful operation of large transmission systems cannot be overemphasized, and the minimizing of the effects of voltage disturbances caused by flashovers due to lightning is of importance. In eastern territory lightning is a major and uncontrollable source of trouble and is the most complicated and least known phenomenon. As a result, the power industry has before it the big problem of lightning research—what lightning is, how to handle it, and how to apply this knowledge in obtaining better line performance.

The comprehensive collection of operating data, supported by data from surge voltage recorders, laboratory research, study, and correlation of facts will undoubtedly permit, within a few years, a systematic solution of transmission problems.

The surge voltage recorder is a big and important tool in lightning research in the field. It permits, with certain limitations, the study of lightning potentials, wave shape of impulses encountered on transmission lines, attenuation, effect of overhead ground wires, etc. It throws some light, also, on the little known phenomenon of the relation of lightning and power arcs.

Of course, the value of the data resulting from the study covered by this paper, obtained during a short period of time, should not be overestimated, and deductions so drawn cannot be considered as indisputable facts. On the other hand, the possibility of obtaining a mass of rather conflicting data at the outset should not discourage further studies, as its dependability will increase with the length of period observed, *i. e.*, with the number of lightning seasons.

## THE WALLENPAUPACK-SIEGFRIED LINE

The terrain crossed by the Wallenpaupack-Siegfried Line is mountainous, quite rugged, rocky, and timbered at its northern end where a maximum altitude of 2100 ft. is attained. Rolling farming country prevails at the southern end. When excavations for the tower footings were made, it was found that over a large portion of the line, the material removed consisted of broken or loose rock which was very difficult to drill or bore. The ground and tower footing resistance averages 50 ohms, with a maximum of 325 ohms on the mountain tops.

---

[2] Overhead System Reference Book, N. E. L. A., p. 479, Table 122.

Table I gives the general characteristics of the line,[3] and Fig. 2 indicates the terminal connections. Table II contains pertinent information about the terminal apparatus, and Fig. 2 is the one line diagram. Fig. 3 shows the standard "A" type of tower. Fig. 4 shows the suspension insulator assembly with ring and horns.

During the summer of 1927 (May-July) two overhead ground wires were installed for the approximate distances of 20 miles at the Wallenpaupack (northern) end of the line and of five miles at the Siegfried (southern) end.

### SURGE VOLTAGE RECORDERS

The surge voltage recorder study was made cooperatively by the General Electric Company and the Pennsylvania Power & Light Company. The former furnished a number of surge voltage recorders which the latter installed and serviced throughout the seasons. The data from the instruments were analyzed, and were correlated with the system operator's log and weather reports.

TABLE I

GENERAL CHARACTERISTICS OF THE WALLENPAUPACK-SIEGFRIED LINE

| | |
|---|---|
| Frequency | 60 cycles |
| Voltage— | |
| Between phases | 220,000 volts |
| Phase to ground | 127,000 volts |
| Normal crest volts to ground | 180,000 volts |
| 60-cycle flashover (dry) | 600,000 volts |
| Line insulation flashover at lightning voltages, approximately | 1,800,000 volts |
| *Protective gaps at stations—flashover at lightning voltages | 1,300,000 volts |
| Circuits | 1 |
| Right-of-way | 100 ft. cleared and danger timber cut |
| Length | 65 mi. |
| Type of construction | Steel tower |
| Configuration of conductors | 22.5 ft. flat |
| Height of conductors at tower | 65.7 ft. |
| Height of ground wires at tower | 75.5 ft. |
| Average span | 1,100 ft. |
| Maximum span | 2,400 ft. |
| Conductor | 795,000 cm. A. C. S. R. |
| *Ground wire—two | 184,000 cm. A. C. S. R. |
| Insulators— | |
| Locke No. 7500 high strength unit: | |
| Suspension assembly | 14 units |

| Wallenpaupack | None |
| Siegfried | None* |
| *Lightning Arresters*: | |
| Wallenpaupack | None |
| Siegfried | None |

NOTE. All switching of the energized line is done from 11 kv. and 66 kv. side of transformers at Wallenpaupack and Siegfried respectively. Neutral dead grounded at each transformer station.

*Three 220-kv. oil circuit breakers placed in service in 1928 with the advent of the Siegfried-Philadelphia 220-kv. line.

The instrument was connected to the line through a capacitance potentiometer consisting of a string of 20 Locke No. 7500 disk insulators, one end of which was connected to the line and the other to ground. The instrument potential was obtained by a connection to the cap of either the second, third, or fourth insulator from the grounded end of the string depending upon potentiometer ratio desired (see Tables III and IV).

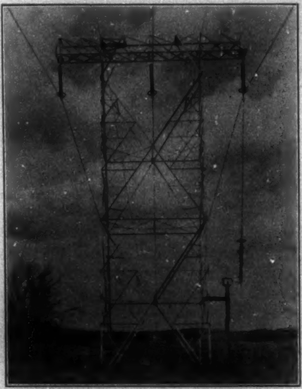

FIG. 3—TYPICAL SURGE-VOLTAGE RECORDER INSTALLATION

Type "A" tower potentiometer assembly and surge-voltage recorder installation

A typical surge voltage recorder installation is shown in Fig. 3. The recorder is installed on an elevated platform, which makes it inaccessible to unauthorized persons. Provision for grounding the instrument when it is serviced as well as other features are incorporated to make the installation safe. This arrangement of the recorder in its sheet metal housing results in a ratio of 60 to 1 between line voltage and instrument voltage for the 20-4 insulator combination, a ratio of 70 to 1 for the 20-3 insulator combination and 90 to 1 for the 20-2 insulator combination. These ratios were determined in the High Voltage Laboratory of the General Electric by calibrating an assembly similar to the field arrangement by impression of surge voltages of known magnitude and wave form. The operation of the surge voltage recorder was fully described before the Institute.[5]

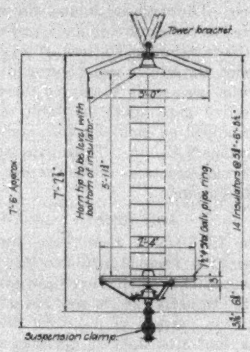

Fig. 4—Wallenpaupack-Siegfried 220-Kv. Line

Single string insulator assembly

The Lichtenberg figures recorded on the photographic films of the various instruments were interpreted as to magnitude, nature, and time of occurrence. Simultaneous registrations on several instruments located at different points along the line have been grouped together and designated as a single surge. The magnitude of the surge voltage on the instrument was determined by figure size, and the magnitude of the surge voltage on the conductor was obtained by multiplying the recorded instrument voltage by the potentiometer ratio. All surge values given in this paper refer to the voltage between the line conductor and ground.

## 220-Kv. Operation of Recorders During 1926

The 1926 study will be touched upon briefly to give a more complete perspective of the experience with the line under study.

During the 1926 season, the line was operated in two distinct periods, from April 23 to August 14 at 220 kv., and from August 15, 1926 to March 13, 1927, at 66 kv.

The locations of the instrument were so arranged as to obtain a maximum of data from the limited number of instruments. From Fig. 2 and Table III it may be seen that on phase *A* there were instruments at each end with three along the line at approximately equal intervals. Phase *B* was equipped with instruments only at each end. Table III also contains information on potentiometer ratios used.

During this period a number of severe lightning storms passed over or near the line. Before the installations of the instruments, five trip-outs were recorded, and after thirteen trip-outs. After all, except two apparatus trouble trip-outs, the line was returned to service at will after approximately one minute interval. Of these eighteen trip-outs, one was accidental, two were caused by apparatus troubles at Wallenpaupack, two resulted from flashovers between conductor and yard structural steel at Siegfried during lightning storms, and the remaining thirteen were probably caused by line insulator flashovers. At the end of the summer season, a careful examination of each insulator string (by climbing towers) disclosed a total of 24 flashed insulators strings. It was impossible to detect most of these flashed insulators from the ground on inspections made after each trip-out. The insulator flashovers resulted, in most cases, in a slight pitting of caps, rings, and horns, and burned and chipped spots on the porcelain, but in no case was an insulator damaged seriously.

On Fig. 5 is plotted the number of surges against surge magnitude. Of the total of 30 lightning surges recorded, 9 were 10 times normal. Switching resulted in 19 surge records with less than 3 times normal voltage. In addition, there was a total of 14 surges

arising from unknown causes, having a maximum value of 1.5 times normal.

### 66-Kv. Operation of Recorders during 1926

The 66-kv. operation necessitated a change of insulator potentiometer ratio. Table III shows the changes made and the location of the instruments. In changing from the 220-kv. to 66-kv. operation, the line insulation was also changed from a 14-unit string to a 4-unit string by short-circuiting ten of the insulator units. This reduction of line insulation extended for distances of three miles from Wallenpaupack and of three miles from Seigfried. With the exception of the installations at tower 17-1, the line insulation at each surge recorder station and at one tower on either side was similarly reduced.

A total of three 66-kv. trip-outs was caused by lightning flashover of insulators at tower 1-2 at the Wallenpaupack end on which ten units had been short circuited. Surge voltages recorded showed that a maximum of ten times normal voltage occurred during these trip-outs. The records from the station at tower 17-1 showed, however, a voltage 29 times normal (based on 66-kv. line voltage), or 1560 kv. This appears to demonstrate that the insulation to ground is a factor in the determination of the maximum voltage to which surge voltages due to lightning may arise.

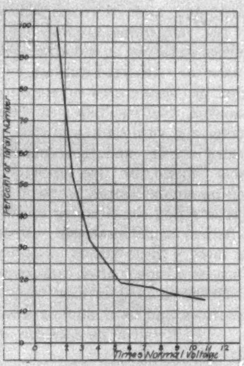

Fig. 5—Magnitude of Surge Voltages 1926

### Preventative and Protective Measures

To secure greater safety to the apparatus against lightning surges of dangerous magnitude, two protective measures were adopted during the spring of 1927:

1. The installation, immediately adjacent to the terminal stations, of lightning protective or spillway gaps of approximately 1300-kv. impulse flashover, and
2. The installation, for distances of approximately five miles, at each end of the line of two overhead ground wires.

For the purpose of studying the effects of overhead ground wires and to further reduce the insulator flashovers, an additional 15-mi. section at the Wallenpaupack end of the line was equipped with these ground wires. Thus the line was protected by ground wires for 20 miles at the Wallenpaupack end, and for five miles at the Siegfried end, leaving the middle section of 40 mi. unprotected. (See Fig. 2). The 20-mile section contains the highest in point of altitude, and in 1926 more than 50 per cent of insulator flashovers occurred on this part of the line. The overhead ground wire was metallically connected to the station grounds, and at the ends away from the transformer stations, it was also effectively grounded through a nest of ground rods. No special provision was made to ground the tower legs.

The protective gaps took the form of insulator assemblies equipped at each end with standard rings having separation of 42.5 in. These gaps were located on the transformer structures and on the first suspension towers at both stations.

### 1927 Study

During the 1927 season there were three distinct periods of operation: From March 13 to May 27, the line was operated at 220 kv. without overhead ground wires; from May 27 to July 25 it was deenergized and grounded for the purpose of installing the overhead ground wires; and after July 25 operated at 220 kv. with two overhead ground wires as described.

*Location of Recorders.* By the close of the season, a

†"20–3" denotes: 20 disk units between line and ground, with the recorder connected to the cap of the 3rd unit from the ground end.

total of 34 instruments was connected to the line as shown on diagram, Fig. 2, and Table IV. Of this number, 26 were coupled to the line through insulator string potentiometers, and 8 were coupled through two special capacitance transformer bushings. These bushings were located on phase *A* near each transformer station. Both bushings were installed after the close of the lightning season and are not shown on Fig. 2 or Table IV.

Table IV shows the potentiometer ratios used.

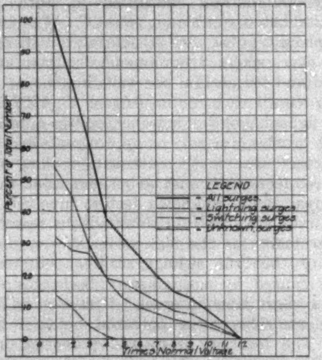

Fig. 6—Surge Classified by Origin 1927

*Nature of Surge Voltages.* The Lichtenberg figures recorded were classified according to their character, namely, Type I, II, and III,[6] *i. e.*, very slow, medium, and very abrupt. As practically all of the surges were of Type II, these were further classified as highly damped (HD) and slightly damped (SD).

TABLE V
ORIGIN OF SURGE VOLTAGES
1927

| Origin | Number | Highest crest value | |
|---|---|---|---|
| | | Times normal | Kv. |
| Lightning | 48 | 11.7 | 2100 |
| Switching | 21 | 4.0 | 720 |
| From unknown causes | | 7.0 | 1260 |
| (a) HD | 29 | 4.9 | 880 |
| (b) SD | 51 | 11.7 | 2100 |
| Total | 149 | .. | .. |

The "highly damped" figures are interpreted as being produced by a surge voltage which lasts for only a few reversals of polarity, such as less than five. The "slightly damped" figures are of uncertain origin. They appear to be formed through the continuous application of alternating potentials for the duration of several seconds (long enough to produce film fog). During the period the line was grounded and deenergized no SD figures were recorded. In this period, however, HD figures were quite frequently recorded during lightning storms. This tends to indicate that the normal line excitation is required to produce SD figures.

During the 1927 investigation a total of 149 surges was recorded, ranging in magnitude from 1 to 11.6 times normal (180 kv. to 2100 kv.).

Correlation of the surges with weather and operating data indicated that many of the disturbances had been produced by lightning or switching. Others are of uncertain origin and have been classified as "from unknown causes." Table V and Fig. 6 show the number and maximum voltage of surges classified according to origin.

*Lightning Surges.* Fig. 7 shows that 56 per cent of the lightning surges exceeded five times normal. The classification as to polarity shows that there are comparatively few unidirectional surge voltages, although their magnitude may be quite high. The majority of lightning surge voltages on this system were oscillatory, with no definite tendency for either the positive or negative wave to be higher.

While the size of figures obtained is indicative of crest voltage values and some information relative to the rate of voltage rise may be obtained from figures characteristics, it is not possible to determine other factors such as relative shape and duration.

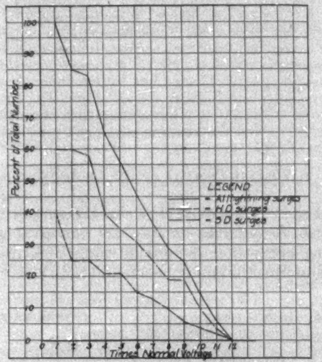

Fig. 7—Lightning Surges 1927

The curves of Fig. 7 show the relation between number and magnitude of surge voltages recorded. On Table VI it may be seen that all unidirectional voltages recorded have HD characteristics. Negative polarity prevails in the HD oscillatory surge voltages 9 out of 13 cases. The SD figures, however, show only two of the negative polarity out of a total of 30. The HD

| 3. H. C. V. Positive and Negative equal | 21 | 11.6 |

*H. C. V.—Highest crest value.

figures in no case show equal magnitude of positive and negative voltages, whereas 20 out of the 30 oscillatory SD surge voltages are of equal positive and negative value.

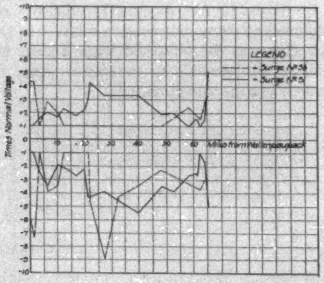

FIG. 8—VOLTAGE PROFILES OF HD LIGHTNING SURGES

TABLE VII

COMPARISON OF SURGE VOLTAGES RECORDED AS TO THE POSITION ON THE TOWER

1927

| Phases | Highest crest value times normal<br>A | <br>B | <br>C |
|---|---|---|---|
| At Wallenpaupack—Tower 1-3 | | | |
| Average voltage | 5.7 | 7.0 | 5.4 |
| Maximum voltage | 7.4 | 7.0 | 9.3 |
| At Siegfried—Tower 65-5 | | | |
| Average voltage | 4.8 | 5.4 | 3.4 |
| Maximum voltage | 7.4 | 11.6 | 4.8 |

Fig. 8 shows the profiles of typical HD surge voltages. Surge No. 38 occurred on July 26 during a general lightning storm after the ground wires were installed. The transformer oil circuit breakers at both ends tripped with ground current indication at both stations. Relays indicated trouble on phase *C*. The protective gap on phase *C* at the yard structure at Wallenpaupack flashed over, where a number of insulator units was blistered and the shell of one unit broken.

Surge No. 51 occurred on August 13, 1927, during a general lightning storm; however, no trip-outs followed.

These profiles give only an approximate and possibly an incorrect idea of the attenuation along the line. In this connection, it must be borne in mind that there are a great many unknown factors involved. While these curves are based on simultaneous recordings on the instruments as the film moves slowly, there is a possibility that the voltage readings obtained were actually caused by a number of discharges occurring within a short time interval. Further, the recorder actually measures surge potential between line and tower. The location of neutral potential or "good ground" is uncertain. In dealing with surge voltages of very steep wave front, ground resistances, although low, may be effective in determining potentials between line and tower. The position and extent of cloud charge is also unknown.

Due to the short period of operation with the overhead ground wires, it would be premature to draw definite quantitative conclusions.

The comparison of voltages recorded relative to the position on the tower is not definite enough to permit drawing conclusions (Table VII).

During the 1927 season, the line tripped out eight times. One trip-out was caused by an accidental ground on the 66-kv. bus at Siegfried and produced only a small switching surge. The remaining seven trip-outs occurred during lightning storms but only

TABLE VIII

TRIP-OUTS DURING LIGHTNING STORMS

| 6 | 7-26-27, 5:14 P. M. | Same as No. 5 | 1-0 | Not recorded | .. | .. |
| 7 | 7-27-27, 3:55 P. M. | Location unknown | .. | + 5.3<br>− 5.3 | 48-3A | HD Oscillatory |

five surges are directly correlated to respective trip-outs. Due to the very short intervals (2 and 5 min.) between two trip-outs at two different times and due to the slow movement of the film, the surge record on the film registered only one surge each time. Table VIII gives the surge voltages correlated as to trip-outs and location of failures.

*Surges Due to Switching Operations.* Twenty-one surges which coincided with normal switching operations were recorded. Frequently switching produced no records on the surge voltage instruments. This fact is probably due to the low tension switching. The majority of switching operations which produced records were those caused by energizing the line. The maximum value recorded at any time was 4.0 times normal and all were of the HD nature. Most of the switching surges were recorded simultaneously at several stations, although never at all stations.

*Unknown Surges.* Some of the surges of unknown origin are thought to have been caused by lightning storms not observed by station operators.

### CONCLUSIONS

1. During the investigations of 1926 and 1927 surge voltages of a magnitude of 2100 kv. were recorded during lightning storms.
2. The majority of surge voltages due to lightning were oscillatory, although a few HD unidirectional surge voltages were recorded.
3. The highest voltages recorded check fairly well with the prediction made from results of insulator calibration in the laboratory.
4. The line insulation apparently limited the magnitude of lightning surge voltages.
5. Not all of the maximum lightning surge voltages caused power arcs.
6. No definite or reliable information was obtained on attenuation.
7. The quantitative value of protection afforded by the overhead ground wire cannot be deduced from the limited data.
8. The highest surge voltages correlated to switching was four times normal (720 kv.), with practically all surges produced by energizing the line. All such voltages were of the HD nature.
9. Many surge voltages were recorded with no possibility of assigning a definite cause to them. These voltages reached an extreme magnitude of 11.6 times normal (2100 kv.).

### FUTURE STUDY

The surge voltage recorder study is being continued in 1928 and it is expected that more data will be obtained than in previous years. The 220-kv. switching also may furnish some valuable and interesting information. Furthermore, with the assistance of laboratory research, it may be possible to determine the relation and condition under which a lightning flashover will be followed by a power arc. This information is of importance in designing lightning proof lines.

Acknowledgment is made to Messrs. C. M. Foust, A. L. Price, F. B. Menger, and W. R. Kleckner for analyzing and correlating the surge voltage data, and to Messrs. A. E. Silver, W. W. Lewis, E. S. Lee, W. E. Lloyd, Jr., and C. A. Jordan for directing the study and criticizing this paper.

## Discussion

### PAPERS ON SURGE-VOLTAGE INVESTIGATION

(LEWIS, DILLARD, HEMSTREET AND EATON, SPORN, SMELOFF)

DENVER, COLO., JUNE 26, 1928

**J. F. Peters:** The authors mentioned three types of potentiometers used for this purpose. Mr. Sporn draws some valuable deductions from his experience with two types. Mr. Smeloff refers to the third form, the high-capacitance transformer bushing, in connection with his work during 1927. During one of our voltage investigations we used a condenser-type bushing with a tap brought out from the next-to-bottom condenser layer as a potentiometer. The results were entirely unsatisfactory. Due to the high capacitance of the bushing the disturbances for the duration were greatly modified in magnitude as indicated by direct comparison with the results from a ring-type potentiometer in the same station, and I would therefore suggest that in making connections to the line, care be taken not to get too high a capacitance in the potentiometer.

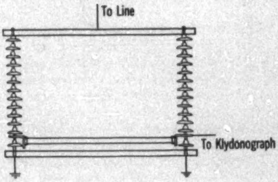

FIG. 1

**J. H. Cox:** The papers presented here are particularly gratifying to the writer, as they add additional weight to most of the conclusions, on the same subject, presented by him, in coauthorship with Messrs. McAuley and Huggins, before this Institute at the Midwinter Convention in 1927.[1]

Mr. Sporn has made an important contribution on the matter of potentiometers. In measuring surge voltages on high-voltage lines, a potentiometer is necessary. Theoretically, either a pure resistance or a pure capacitance is satisfactory. Practically, a resistance is not satisfactory where it must withstand sustained line voltage, and also, for high voltages its physical dimensions become so large that its physical capacity disturbs the voltage distribution. Therefore, the capacity potentiometer is the only one available, and the capacities should be so arranged as to eliminate the effect of any resistance path.

Mr. Sporn has discussed the effects of the leakage path in the insulator-string potentiometer. In another test, with which the writer was connected, pipe-type potentiometers were used but different conditions permitted the desired ratio with the use of only two pipes in the lower group instead of three as shown in Mr. Sporn's paper. The potentiometer used is shown in Fig. 1 herewith. It will be noticed that the klydonograph is tapped across the leakage paths of the two supporting insulator strings.

---

[1] *Klydonograph Surge Investigations*, by Cox, McAuley, and Huggins, A. I. E. E. TRANS., Vol. XLVI, 1927, p. 315.

It was hoped that the capacity of the pipes would be large enough to predominate over the leakage coupling under all conditions. However, it was found that during rainstorms slightly damped figures, of the same nature as those produced by the insulator string potentiometer, were recorded. This was on a grounded neutral system where sustained oscillatory surges had never been recorded in two years' tests with ring-type potentiometers. This undesirable feature was eliminated by short-circuiting the leakage path about the klydonograph in the manner shown in the accompanying Fig. 2.

The pipe-type potentiometer was designed to provide a form more convenient than the ring-type from an installation point of view. The parts are easily provided. Fig. 3 herewith shows a form of pipe-type potentiometer which has recently been devised, which eliminates entirely the leakage path from the klydonograph circuit, and which is even more convenient to install than that shown in Fig. 2.

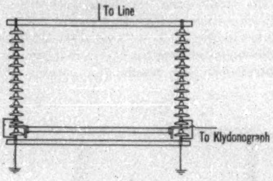

FIG. 2

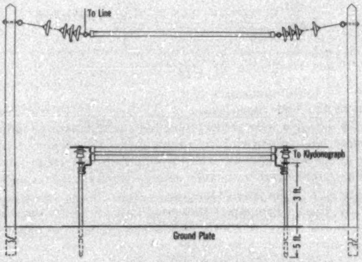

FIG. 3

The writer heartily agrees with Mr. Sporn in his decision to omit all S. D. (slightly damped) figures in his discussion of results. The evidence is quite conclusive that these figures were the result of a change in the ratio of the particular potentiometer used, under certain conditions, and to include them in data on which conclusions are based is misleading. With the exception of the S. D. figures, probably the data furnished with an insulator-string potentiometer are sufficiently accurate. However, the principal object of klydonograph tests is the recording of lightning voltages. These S. D. figures occur during rainstorms which usually accompany lightning. Figures occurring at this time, of course, obscure the legitimate figures recorded by voltages actually existing on the line. Therefore, with the elimination of the S. D. figures some of the most desired data are automatically eliminated. Hence, although the cheapness of the insulator-string potentiometer makes it particularly attractive, the writer does not feel that its use is justified.

**F. C. Hanker:** The need for more accurate information on the fundamentals of lightning phenomena has long been recognized, but no reliable recording device was available until the development and introduction of the klydonograph by Mr. Peters in 1923 made possible for the first time, the measurement of lightning and other surge voltages with a reasonable degree of accuracy. The characteristic which makes this device of particular value for the work, is that while it will operate for a week or more without attention, it will record the magnitude and polarity of voltages, the duration of which may be less than a microsecond and which may occur at any time.

It is desirable to obtain more complete information on surges caused on transmission lines than it is possible to obtain with the klydonograph. We secure reasonably accurate information on the magnitude within the limits of line insulation but in order to develop remedial devices more completely, it is important to establish other characteristics such as shape of wave front, duration, shape of wave tail, polarity, and effect of location of the stroke.

The Westinghouse Company, in cooperation with the Aluminum Company of America, is starting a lightning investigation in Tennessee using the form of cathode-ray oscillograph which was announced by Dr. Nordinder in his papers presented before the Franklin Institute and at the 1928 Winter Convention of this Institute.[2] In both of these presentations, he has given records of actual surge voltages recorded on an operating transmission circuit. This instrument, with other accessories used in the investigation, will yield all the information which has been lacking from the extensive klydonograph surveys that have been made during the past two years.

Due to the uncertainty of the occurrence of lightning, the complete story cannot be obtained in a short time. Existing circuits have limitations in dielectric strength that make it impossible to establish definitely the maximum voltages that are impressed on the circuit. It is expected that oscillograms obtained with the instrument now in operation will give sufficient data to permit establishing the complete wave form with a reasonable degree of accuracy and will point the way toward future procedure in obtaining the complete answer to the problem.

**L. L. Perry:** The papers show that on well designed transmission lines surges as high as ten or twelve times normal voltage must be expected in lightning country.

With regard to these conditions, I should like to ask Mr. Lewis these questions:

1. Would further developments in choke coils materially reduce the voltages reaching the arresters? Possibly it might increase.
2. To what percentage of normal voltage will a modern arrester limit the surge?
3. Does he recommend eliminating the arrester and making circuit breakers and transformers so that their insulation will withstand ten or twelve times normal without flashover or failure?

I should also like to ask him if he can supplement Table IV by the average height of conductor for line H-8?

I should also like to ask Mr. Foust from the operating records what percentage of trip-outs on one circuit involve the second circuit?

**A. C. Austin:** It is interesting to note that some of the conclusions drawn through a study of the performance of the insulator are apparently corroborated by the recent studies. Some years ago it was evident that where a line was under-insulated or had a number of faulty insulators, switching surges of appreciable magnitude apparently traversed the whole line, whereas lightning was localized. This was evident from the fact that a line might pass through a number of severe electrical storms before tripping out. In trying to energize the line again, however, it was sometimes necessary to avoid all switching surges and build up the voltage before the line would stay in. The conclusions reached were that the much higher disturbances produced by lightning were localized so that they did not affect a faulty insulator which was readily picked out by the lower voltage surge occasioned by switching, but which affected practically the whole line.

---

[2] *The Cathode Oscillograph as Used in the Study of Lightning and Other Surges on Transmission Lines*, A. I. E. E. Quarterly TRANS., Vol. 47, April 1928, p. 446.

The need of more exact information as to the wave front or exact history of the disturbance on the line is still apparent. Tests in the laboratory indicate that many flashovers may take place at from 50 per cent to 60 per cent of the crest value occurring on the tail of the wave. The cathode-ray oscillograph shows that the flashover of an insulator may take place under a variety of conditions, depending upon the magnitude and duration of the wave. Both line troubles as well as tests in the high-voltage laboratory indicate that not only will the wave front produced by lightning vary considerably, but that the wave front for a single discharge is likely to vary over a very wide range.

To obtain records on the transmission line for actual conditions is not an easy problem, for a record which will cover a period of from 10 to 50 microseconds may not give the information on certain parts of the wave or voltage rise in sufficient detail. While apparently perfect oscillograph records may be obtained, it is necessary that these records are of the condition set up on the line by lightning and not a record of a disturbance set up in or greatly modified by the leads or coupling to the transmission line.

Tests made during the past year go to show that potentials above 800 kv. peak drop very rapidly and are usually attended by an oscillation during the decay of the charge. In most cases the discharge does not develop to the point where a power arc will follow until 10 or 15 microseconds after the crest is reached, the actual flashover taking place at a voltage of not more than 50 or 60 per cent of the crest voltage. From this it would appear that any scheme which will increase the time lag of the insulator or increase the attenuation will result in lower flashovers. On the other hand, tower or insulator construction or the attachment of electrodes which will reduce the time lag will result in increasing the number of flashovers.

The steepest wave fronts, although reaching very high values, may not cause as many flashovers as wave fronts at very much less slope and magnitude. This is particularly true where the dissipation or absorption of the charge is high.

**Philip Sporn:** Mr. Lewis's statement that the voltage on a line is limited by the flashover strength of the line insulators, ought to be modified, I think, to include not only the insulators but the structure itself, which, in turn, of course, includes the connection to ground. Mr. Peek has shown that the flashover value of a string of insulators increases with the amount of resistance to ground in series with that string and it is very important that in all discussions this be kept to the forefront as on no other basis have we been able to date to explain many phenomena that are clearly explained this way.

As regards the attenuation and the formula presented by Mr. Lewis, this is a fine attempt to get attenuation down on a mathematical basis but I do not believe that sufficient data have been gathered together for anybody to be able to say definitely that this is an exact and proved relationship. Some of the data that we obtained on investigations not mentioned in our paper would seem to indicate a much higher attenuation on lightning surges than the one given in the equation developed by Messrs. Foust and Menger. It is to be hoped that the work which is being carried on this year will give us more data on the subject.

**C. M. Faust:** Having been closely identified with the analyzing of the films from the surge recorders, I thought it might be somewhat interesting to try to explain and amplify and clarify possibly our methods of attack. For that purpose I have prepared a little chart. All surges were subject to two classifications, one with reference to nature or polarity characteristic and the other with regard to wave front. This chart may serve to explain these classifications.

All surges—Nature of Polarity Characteristic
- Unidirectional
  - Positive polarity
  - Negative polarity
- Oscillatory
  - Highly damped
    - (Predominantly pos.)
    - (Predominantly neg.)
  - Medium damped
  - Slightly damped

All surges—Type
- I. Slow wave front
- II. Medium wave front
- III. Fast wave front

Now with regard to this sort of classification and with particular reference to unidirectional or highly damped surges, there are two cases of field registration of interest.

1. Surges measured at only one station.
2. Surges measured at several stations.

Under the first case, a surge was readily classified with reference to the above chart. With regard to the second case, however, there were instances wherein station records disagreed, for example, indicated unidirectional at one station and oscillation but highly damped at others. With regard to the general classification of such a surge, two methods were followed:

1. Surge classified as oscillatory when registered as oscillatory at any one station.
2. Surge classified as to nature with regard to the polarity characteristic at the station where highest voltage registration was obtained.

The second classification appears to have particular advantage if the polarity of the induced charges is of interest. First, because reflection conditions may complicate the record at remote stations and secondly, because the switching surge due to the automatic trip-out cannot be separated from the lightning surge itself.

As both the above methods of classification have been used by the authors in preparing their papers, comparison of results must be performed with this in mind.

**J. F. Foote:** The formula for the attenuation of surges is probably of correct form for surges of a particular range of frequency. The results showing wide extent of M. D. surges and equally extensive H. D. switching surges would indicate that some other factors than voltage and line constants may affect attenuation. Would not further investigation of the possible effect of varying wave fronts probably show that the formula should include a wave front term or factor?

In stating that we may expect small trouble from M. D. surges because they are usually of less value than the impulse flashover of insulators, should we not recall that the M. D. surge may not be similar to the impulse wave upon which the insulator flashover value is based? It would seem reasonable to expect the flashover value of the insulator under the stress of such waves to be intermediate between the value obtained with an extremely steep wave front and that obtained at 60 cycles. In other words, the flashover value may be anywhere within the range of, say, three times to ten times the normal voltage, depending on the frequency of the surge. Thus if M. D. surges of moderately high frequency be encountered it is conceivable that flashovers may occur even at moderate amplitudes.

The conclusions regarding the effectiveness of choke coils do not seem entirely justified by the data given. That is, if it is meant that the amplitude of the voltage surge continuing beyond the choke coil tends to be in the order of 25 per cent less than the surge would be if the coil were omitted, the method of measurement used is inconclusive, since the voltage measured on the line side of the choke coil is not the voltage of the impressed surge, but this voltage increased by the partial reflection of this wave by the coil.

A choke coil is not a unidirectional valve nor is it more than a partial reflecting agent. Part of the impressed wave is probably reflected and the remainder passes through the coil. Should the transmitted surge then encounter another reflecting agent, as it usually will, in the way of a transformer winding or open switch, full or partial reflection of this wave will occur. If the distance between the choke coil and the second reflecting agent be short, attenuation will be small and the surge will strike the choke coil from the rear, as it were, being again partially reflected. Thus it is very possible that oscillations may build up in the short section beyond the choke coil, producing voltages in excess of the original surge.

The data in Mr. Sporn's paper indicate that in four out of ten cases this voltage did build up to greater values than even that of the partially reflected surge outside the coil. The other six show lower voltages beyond the coil than the reflected voltage in front of the coil, but it is not shown what the unreflected voltage might have been, and possibly the reduction was not a reduction in fact.

For many years the lightning-arrester engineers have regarded the choke coil as an accessory to assist in quick and certain gap break-down. However, the arrester is usually purchased to protect station, not line equipment, and to isolate such equipment from the arrester by the choke coil seems illogical in view of the considerations noted above.

**Fred O. McMillan:** It is interesting to note in Mr. Lewis' paper that the only points that are at any considerable distance from the drawn curve of Fig. 10 are those for surges 38 and 40, which were on the Pennsylvania Power and Light Company's system. Since this company's line has design constants different from the New England Power Company's line, it is to be expected that the constant $k$ for equations (1) and (2) would be quite different for these two surges.

I should like to ask Mr. Lewis to explain more fully why the voltages on the ground wire and tower were comparatively low. One would expect that in the case of very steep wave fronts the voltage rise would be very high until the reflected wave from ground wipes out the initial wave. It would appear that the only explanation of the low ground-wire voltages found must be in having waves of relatively sloping wave fronts.

**Harold Michener:** The Vincent 220,000-volt line was built without a ground wire. The southern half of it has been in operation for nearly two years and the complete line since last November.

Two months ago we had about six flashovers from lightning. We decided to put on two ground wires. We were careful, however, to tell our management that we didn't expect the ground wires to stop all the trouble from lightning.

The observations made at the time were rather interesting. Some of our men were working on a road near the location of the trouble and they reported that they could see streamers of fire, corona streamers, of some considerable length extending from the wires before the flashover occurred. The storm went on across that section of the old Big Creek lines immediately north of Vestal substation and caused no trouble on them.

This was pointed out as showing the value of the ground wire under the supposition that the two parallel old Big Creek lines were each equipped with one ground wire in this section and that the Vincent line was not. However, this proved to be the section in which there is about a 20-mi. gap in the ground wire on one of the old Big Creek lines. What we really had was the Vincent line in trouble from lightning, the storm passing on across the old Big Creek lines with lightning striking near on both sides of them and causing only fluctuations in the meters at Vestal even though one of them did not have a ground wire in this section.

Another thing of interest in that section of the old Big Creek lines through the San Joaquin Valley is that the only case of lightning trouble we have had there was on a tower equipped with two ground wires.

These facts, as we see them, only go to show that we cannot place too much dependence on the ground wires, and the fact that we are putting ground wires on the Vincent lines since we had the trouble with lightning shows we believe they will be of some benefit.

I rather expected to find more unanimity of opinion in regard to ground wires. I had gained the impression during the last two or three years that almost everyone was swinging to the belief that ground wires are a real protection. I think they are, but still there are things that seem a little doubtful about it.

**E. S. Fields:** The Union Gas and Electric Company of Cincinnati has been experimenting with a device for interrupting the flashover current before the protective relays operate to cause a trip-out of the transmission circuit with which some of you are probably familiar. Fig. 4 herewith shows the device in the present stage of its development for 66-kv. construction. A standard grading ring is installed at the conductor at the bottom of the insulator string. At the top of the string two 33-kv. expulsion fuses are installed in the position of arcing horns.

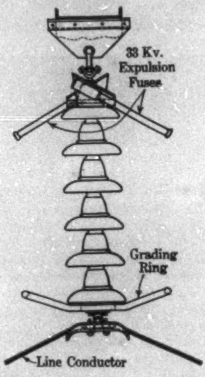

FIG. 4

In order to insure that the flashovers will take place from the end of the fused horn to the grading ring, the length and position of the fused horns and the dimensions of the grading ring have been determined from experiments conducted in the high-voltage laboratory with the impulse generator.

When a flashover occurs it strikes from the tip of the fuse to the grading ring. The power current that follows is interrupted by the operation of the expulsion fuse, usually in the first half cycle.

Sixty miles of 66-kv. line were equipped with this device in 1926 and the performance of this initial installation has led to the installation of the device on fifty miles of additional 66-kv. circuit this year.

During the summer of 1926, 77 per cent of the flashovers occurring on the original 60 mi. of 66-kv. line were interrupted by the fuses without service interruptions on the circuit. So far only 66-kv. circuits have been equipped with this device.

**A. O. Austin:** Both Mr. Smeloff and Mr. Michener made very interesting statements in connection with the use of the ground wire. Mr. Foote also mentioned the danger from flashover for voltages much lower than the crest voltages induced by lightning. It is these lower voltage flashovers which offer the most serious problem for the very long high-voltage transmission line.

It is interesting to note that the recent klydonograph records as well as tests in the laboratory go to show that the attenuation or dissipation of the charge is very rapid at the higher voltages, but that the attenuation drops off very quickly as the voltage is reduced. By applying this information to the operation of the line we are able to explain some of the apparently contradictory performance of the ground wire.

The ground wire functions primarily through its absorbing electrostatic capacity which tends to keep down the rise in potential for a given charge on the power conductor. While the presence of the ground wire reduces the quantity of the charge, on the power conductor, this is comparatively small where the separation of the conductors is large. Where no ground wire is used, a very high induced voltage or one above three-quarters of a million to one million volts is dissipated very rapidly as corona loss. If in the same installation a ground wire were installed such that the induced voltage on the power conductor would not rise above three-quarters of a million volts below which the corona loss is relatively small, it naturally follows that there would be more energy to set up a surge or traveling wave, which would have greater amplitude at a distance than where a large part of the energy was dissipated. In view of this, the increasing use of low-resistance ground wires must be watched very carefully as their use is likely to have the same effect upon the transmission line as the use of more limber springs and balloon tires had upon the automobile. While balloon tires and more limber springs greatly reduced the shock, it was necessary to provide shock absorbers in order to eliminate the resulting oscillation which otherwise more than offset the reduction in the intensity of the initial shock.

Where the ground wire has the properties of the shock absorber, it will not only reduce the crest voltage or bump, but will dissipate the energy stored in the power conductor.

Where the resistance of the ground wire is low, the current induced in the ground wire by a traveling wave or oscillation will create but small loss so that a low-resistance ground wire will not have the dissipating or shock-absorbing properties of a high-resistance ground wire. If we are to obtain the benefit of a low-resistance ground wire both from the standpoint of reducing the crest voltage and through the absorption of energy in the traveling wave, it is necessary to adopt a new scheme of installation. In this scheme it is proposed to sectionalize and insulate the ground wire, forcing the induced currents over discharge gaps which will dissipate energy. In order that the ground wire may hold down the crest voltage in the vicinity of the disturbance, a shunt gap is provided at the insulated supports. This shunt gap discharges and reduces the potential from ground wire to earth. An installation of this kind not only keeps down the maximum voltage in the vicinity of the disturbance, but can be made to absorb the traveling wave or oscillation. The absorption of energy tends to cut down the time-voltage effect, tending to flash the insulator and thereby reduces the tendency to flash at a distance. The absorption of energy will also be beneficial in keeping down the magnitude of the surge entering the station. From the electrical standpoint, resistance in the ground wire may be of material advantage and where low-resistance ground wires are used, it would seem that provision should be made so that they will dissipate the energy of the traveling waves or oscillations.

Where ground wires are located near stations, attention should be given to developing the electrostatic capacity between ground wire and conductors as far as possible. This increased electrostatic capacity together with the electrostatic capacity of the bus structure and connected equipment will do much to keep down the maximum voltage in the station. It would seem that the increased electrostatic capacity of the station is a much greater factor in keeping down the maximum voltage than the impedance of a choke coil. In extra high-voltage transformers, more dependence is placed in the circuit upon absorbing resistances than upon reactance coils. As a matter of fact, where break-downs are quite frequent with reactance coils, these break-downs have disappeared where absorbing resistances are used. Where an absorbing resistance cannot be placed between the line and a large station, an absorbing resistance can be placed in a ground wire. As the energy must come from the power conductor, the same general result will be accomplished as in the case where the absorbing resistance is used directly in the circuit.

**W. W. Parker:** (communicated after adjournment) I feel in very strong agreement with J. F. Peters' suggestion that the potentiometer used in connection with the klydonograph requires some special investigation and further research. We got some rather startling results from a klydonograph installation on our 132-kv. system last January, which led to some investigations. It was found that positive figures can be produced by sprinkling water over the potentiometer, and by momentarily bridging out one of the insulators forming part of the potentiometer string. Each figure obtained by sprinkling the potentiometer is positive. The rays radiate out from the center with no evidence of any negative figures. Some of these figures are as high as fifteen times normal.

The potentiometer consists of five Faradon condenser-type insulators in series, the klydonograph being connected across the last insulator. The last insulator is approximately ten times the capacity of the others.

**C. F. Harding:** (communicated after adjournment) The data recorded and summarized in the paper by Messrs. Hemstreet and Eaton provide one more distinct advance in the investigation of high-voltage surges and the analysis of their causes. The surge recorders have apparently provided more information regarding the number, magnitude, and locality of such surges upon transmission lines than any instruments have furnished which have been available previous to this time.

However, such an instrument is admittedly very approximate in its quantitative measurement, particularly with respect to the steepness of the wave front and duration of the tail of the surge, and is likely to be qualitatively misleading with respect to initial polarity and indication of the oscillatory nature of the discharge. The large number of surges which were recorded with almost equal magnitude at all stations, apparently having medium damped characteristics and yet rising to 7.7 times normal line voltage and coinciding with switch trip-outs, is, of course, such as to cause the more serious and widespread interruption to service. These should therefore be studied most thoroughly in future investigations. Fortunately, such surges may now be recorded and analyzed by means of the cathode-ray oscillograph and the polarity, magnitude, and duration of the medium and slightly damped tails of the surge may be more accurately determined and studied.

The contribution of this paper to the much discussed subject of the protective value of the ground wire, furnishing for the first time concrete test data of parallel exposures under similar conditions both with and without the ground wire, has been greatly needed to bring to a definite conclusion the arguments of past years which have been based upon exposures of different types in various localities and the resulting opinions of engineers necessarily dependent upon rather meager test data. These test data are significant not only because of their proof of the protective feature of the ground wire, but particularly because of the reduction in the number of surges which ranged from four to eight times normal line voltage and the apparent elimination of those between eight and eleven times normal which appeared upon the parallel line. Furthermore, the importance of thorough grounding of the ground wire at each tower has been demonstrated by the test voltages accumulated at the center of the span.

Although the conclusion is recorded with reference to Figs. 11 and 12 that "no definite relation exists between the magnitude of surge voltages measured and conductor height," it would appear from inspection of these graphs that the upper wire on both lines is withstanding more and higher voltage surges than the lower wires, particularly for surges up to five or six times normal. It would be of interest to know if the original data, or those not included in these charts, tend to neutralize the value of such a conclusion.

**J. E. Clem:** (communicated after adjournment) Mr. Lewis in his paper gives the maximum voltage found as resulting from switching, but gives no data in regard to the length of the wave front. The wave front should be known so that new lines may be designed with enough insulation to withstand these surges. This discussion will present some data which should help in deciding whether 60 cycle or impulse strength applied when considering the voltages produced by switching surges.

In Table V, Lewis gives the maximum voltages found due to switching and in the text states that load switching is not severe and that switching off is more severe than switching on. Although not mentioned specifically the voltages due to opening a short circuit are included in the tabulation. It is also stated that these surges are usually highly damped and therefore of short duration. It is seen from this table that the highest voltage is about 5 times the normal crest voltage line to neutral. Since this ratio is not exceeded over the operating range from 110 kv. to 220 kv. it can be used safely for design.

The accompaning three tabulations give an analysis of switching surges found on three of the systems mentioned in Table V. The data have been tabulated to show the magnitude of the crest voltage and the time to reach the crest; that is, the wave front. The wave front was obtained by the method outlined in Lewis's paper. A study of these data indicates that at the lower voltages the wave fronts are relatively long, while at the higher voltages there might be said to be a tendency toward shorter wave fronts. Although all the surges, except one, above four times normal could have had a wave front as fast as 100 microseconds, it doubtless would be better to consider them all slow and use the 60-cycle flashover strength of the insulators in figuring the number of units required to prevent flashover from switching surges.

These switching surges may happen when the line insulators are wet and this should be considered. For a standard precipitation of 0.2 in. rain per minute the 60-cycle flashover is approximately 80 per cent of the dry flashover. This precipitation is not rain but is really a deluge. At half the standard precipitation the flashover is about 7 per cent higher, according to Peek, and for the ordinary heavy rainstorms is no doubt somewhat higher.

The lightning flashover of a string of insulators is the same wet as dry which indicates that the effect of moisture decreases as the wave front grows shorter. In view of the fact that the surges having a magnitude of five times normal probably have a wave front faster than the 60-cycle wave front, it is quite possible that the effect of rain is somewhat less than at 60 cycles. Also Wade and Smith in an article entitled "Time Lag of Insulators," *Elec. World*, Aug. 18, 1928, give data which indicate that the flashover voltage of suspension insulators obtained with a wave front corresponding to 60 cycles may be somewhat higher than that obtained by the usual method of determining the 60-cycle flashover voltage. These two facts indicate that the ratio of wet to dry flashover for these switching surges will be higher than for 60 cycles. From the foregoing it appears that the dry 60-cycle flashover voltage of the insulators can be used in estimating insulation required for switching surges.

Studies of existing systems have shown that the average line insulation will stand about six times normal voltage. This is enough to withstand any low-frequency disturbances to which the lines may be subjected, whether due to dropping of load, switching, or arcing grounds. It appears that a line insulated for five times normal lag voltage will not flash over during switching transients, but since existing lines have an average of six times, it would be better to use six times normal leg voltage as the required insulation strength at 60 cycles.

**R. H. George:** (communicated after adjournment) The percentage of apparently oscillatory discharges recorded by Messrs. Hemstreet and Eaton seems quite high, but as pointed out, this may be due largely to the limitations of the surge recorder rather than to actual oscillatory surges. Some of these records may result from a series of successive discharges from cloud to earth similar to those illustrated in Dr. Humphreys' book "Physics of the Air," pages 368-372. Dr. Humphreys shows one photograph taken by Larsen with a revolving-mirror camera in which six successive discharges take place along the same path at intervals of from 4 to 10 milliseconds. If such a series of discharges took place in the vicinity of a transmission line, the rapid fluctuations in the field might give rise to records of reversed polarity although the actual discharges were in one direction.

It is quite probable that the question of oscillatory surges on transmission lines can only be solved by the use of the cathode-ray oscillograph, on the use of the oscillograph and surge recorder together.

**W. W. Lewis:** Mr. Perry asked about the effect of choke coils on the voltage reaching the arresters. That is what we are trying to find out in our investigation. All the data we have on the subject at present are given in Mr. Sporn's and my papers. The data are rather confusing and do not indicate definitely whether choke coils are beneficial or not. We are, however, going to use them until we know more about the subject.

Mr. Perry also asked to what percentage of normal voltage a modern arrester will limit a surge. This has been very well answered by Mr. K. B. McEachron in a paper entitled "Protection of Station Equipment on High-Voltage Transmission Lines" which appeared in the *General Electric Review* of May 1928. In this paper it is shown that oxide-film arresters limit the voltage of a surge to certain values which depend on the wave front of the surge. These values vary from about 1 kv. per cell to about 1.8 kv. per cell. The last-named value is the voltage corresponding to the steepest wave fronts, *i. e.*, of the order of one-fourth microsecond. Such a front is steeper than any that we have been able to measure on transmission lines and corresponds with the wave in Mr. Peek's laboratory which we have used as a reference in giving the flashover value of insulator strings.

From this statement it will be apparent that the fewer the cells used, the better the protection obtained. A certain minimum number of cells is required, however, to prevent the arrester from failing under 60-cycle voltage when the voltage runs away due to the dropping of load. If this runaway voltage can be maintained at a low value, then the number of cells may be decreased and the protection will be improved.

Mr. Perry also asked that Table IV be supplemented by the average height of conductor for Line H-8. This average height, I believe, is about 45 ft.

In Mr. Foote's discussion he refers to the 60-cycle flashover value of line insulation as about three times normal. On the average system the 60-cycle flashover is usually about six times normal, *i. e.*, six times the crest value of the line-to-neutral voltage. For example: On Mr. Foote's own 140-kv. system, normal voltage is about 114-kv. crest value line-to-neutral. The 60-cycle flashover of ten standard disks is about 765-kv. crest value, or about 6.7 times normal. The impulse flashover with steep wave is in the neighborhood of 1400 kv. or about 12 times normal. An examination will disclose that the majority of transmission lines are insulated for at least six times normal, 60 cycle voltage, and from 10 to 14 times normal against impulse flashover.

The flashover voltage of a string of insulators varies from the 60-cycle value to a very high value under impulse. Any number of impulse values may be obtained, depending on the steepness of the wave front and the duration of the wave. The figure of 10 to 14 times normal mentioned as impulse flashover is based on a particular wave of steep front and long tail. If we had a steeper wave we might even get a higher value. As shown in Table IV of my paper, the highest voltages recorded in the 1927 investigation vary from 7 to 12 times normal, which check fairly well with the estimated impulse flashover.

In regard to Mr. Michener's discussion: the resistance of the tower footing has a great deal of effect on the operation of the ground wire. If the tower footing has a high resistance the ground wire is, in effect, an insulated wire, and will do very little good in reducing surge voltage.

In the particular territory discussed by Mr. Michener, it might be that the soil is composed largely of sand and rocks. This condition will give a very high tower-footing resistance which not only nullifies the grounding of the ground wire but apparently has the effect of increasing the height of the tower. In other words, a high ground resistance indicates that the water level is considerably below the earth surface and the tower in effect is much higher than indicated by the height above the earth's surface itself. This allows lightning to build up a higher voltage on the conductors than would be expected. Mr. J. G. Hemstreet brought out this effect very well in a paper entitled *Recent Investigation of Transmission Line Operation*, which appeared in A. I. E. E., TRANS., Vol. 46, 1927, page 835.

**J. R. Eaton:** There is one point in connection with safety that has been emphasized in the report on the Pennsylvania Power and Light Company presented by Mr. Smeloff.

The line was grounded at numerous places during the installation of a ground wire. Even with this line grounded at various places, there were very high voltages recorded—I think over a million volts. On the Consumers' line we recorded over 35,000 volts at mid-span of a ground wire, where, of course, it was grounded at both ends of the span.

That certainly emphasizes the necessity of grounding a line at the point where men are working on it, especially under lightning conditions. A ground that is located even a few spans away certainly does not offer adequate protection to men who are working on the line.

Someone asked for an explanation of the fact that surges recorded at mid-span of the ground wire had low values compared with that recorded simultaneously on the line wire. On the ground wire the maximum voltage recorded was 35 kv. at mid-span while at the tower it was several hundred kv. It is possible that the surge originated at some point down the line, and the transient traveled along the conductor without being reduced in value to any great extent, whereas on the ground wire, the section on which the surge recorder was connected was in a weak part of the field and received only a small part of the voltage.

In some recent inspections we have found two distinct kinds of burns on our insulators. There is one type which we feel sure is caused by a power arc. This resembles that produced by laying a cigarette on a varnished surface. That undoubtedly comes from the power arc.

There is another type of burn on the procelain which might be described as appearing as though some thin molasses had been spilled near the cap of the insulator and then run in a narrow stream to the end of the insulator. This type of burn has been observed on insulators which have been flashed over by impulses from lightning generators as well as on insulators in the field. We feel reasonably sure these burns are caused by the lightning discharge itself. Burns of this type are frequently found where the power arc type of burn is also found, indicating that possibly there had been a lightning flashover followed by the power arc.

In some cases, however, every unit in a string will have the lightning burn on the porcelain, showing almost a complete cascade of the lightning discharge, but there will be no power-arc burns at all. That may be an explanation of the fact that in some cases we have recorded very high voltages on lines without having them trip out. Apparently the power arc did not follow the lightning flashover.

**J. G. Hemstreet:** The investigations that are being made on the various transmission systems and in the laboratories are gradually determining exact conditions which create perhaps the greatest hazard to power transmission.

The klydonograph has been of great value in determining the magnitude of the surges set up and has quite definitely shown that surges due to causes other than lightning are not so serious as was thought a few years ago. The results of the klydonograph investigations as shown by these papers have been a little disappointing due to the uncertainty of the meaning of some of the figures recorded. However, this difficulty has been done away with and with the proper type of potentiometer, a better set of records should be obtained by these instruments.

We believe that some of the most valuable information has been obtained by careful inspections of transmission lines and by keeping records of the number of insulator flashovers found by these inspections. The insulator string and its performance under the abnormal conditions in the lines is, in the last word, the real indicator of the severity of the surges that are taking place and it would be well if more of the operating companies would make these careful investigations so that a greater quantity of data will be available for study.

The cathode-ray oscillograph seems to offer a means of securing information as to the steepness of the wave front and other characteristics of the surges that are under investigation. It is our understanding that an oscillograph of this type, together with other instruments, is to be used by the Westinghouse Electric and Manufacturing Company in securing data on one of the high-voltage lines in Tennessee and that the General Electric Company are making a somewhat similar setup on a line in Pennsylvania. The Consumers Power Company in continuing its investigation of lightning disturbances, has obtained the use of a type of cathode-ray oscillograph which has been developed in the High Voltage Laboratory of Purdue University. This instrument will be connected to the lines of this company and it is hoped that more exact information as to the character of the surges on the system will be secured. This, together with the investigation on other systems along the same line, will perhaps give us information that will be of great value in connection with the design of transmission lines and substations.

**Philip Sporn:** Mr. Michener's point with regard to the effectiveness of the ground wire, I think, is very well taken. The papers, as a whole, do not bring out the effectiveness of the ground wire as clearly as do other operating data and I should like to refer Mr. Michener to the series of papers that has been presented during the last three years before the Institute, on the lightning experience that we had with the Philo-Canton line both before and after ground wires were installed, which throw some light on the ground wire's effectiveness.

Mr. Foote brought up a point with regard to choke coils. When we first started our klydonograph layout to study the effectiveness of the choke coils we had pretty high hopes. We thought we would get come definite information either pro or con. The first thing that we ran into was a few surges that came in where we found on one side of the choke coil some 200 kv. positive and on the other side we found the same negative, a reversal of polarity taking place through the choke coil. On going to the next tower out from the station we found that it was still positive. We did not believe this. There are so many surges that can be superimposed one on top of the other, or combined due to reflection, and since the klydonograph records only the one maximum voltage which exists, the limited information that we have obtained so far cannot possibly be conclusive. However, we do believe that this much has been shown. In so far as it can be said that the choke coil is either a benefit or a hindrance in connection with a lightning arrester the data showed definitely that it is certainly no worse than neutral and very often beneficial. Theory, of course, checks that up also.

Mr. Austin made the statement that attenuation is much less rapid with the ground wire than without it. This is obviously not so. He is right if he means that due to the fact that where a ground wire exists the possible amplitude of the wave is initially cut down and therefore the rate of attenuation on this reduced wave is much smaller than it would have been on the wave without a ground wire. Otherwise he is not right, since the ground wire helps reduce the amplitude of the wave by acting as an absorbing medium.

**N. N. Smeloff:** The type of potentiometer used on our system produces slightly damped figures. We have not discarded these figures from our study, but classified them and used them. These uses were made with a reservation, *i. e.*, it is without doubt now established that the slightly damped figures are produced by 60-cycle potential and this type of potentiometer; however, the highly damped figures may be present, but obscured by the slightly damped figures. This has been proved by the fact that during some trip-outs and flashovers of the line, only the slightly damped figures were obtained on the recorder films.

The study during 1928 is more extensive: more instruments and additional 220-kv. line are used. The potentiometers for the surge-voltage recorders have been modified in such a manner that no slightly damped surges are produced that would obscure the recorder films.

It would be rather premature to draw conclusions about the operation of our new 220-kv. line. It went through just about two months of lightning season operation without trip-outs. Surge-voltage recorders are installed and we expect to obtain valuable data. On the old line, Wallenpaupack-Siegfried, we again had several flashovers. The flashovers occurred on the unprotected section of the line as well as on the section where the overhead ground wire was installed. So again we are not in a position at this time, to make any definite conclusions on the value of overhead ground-wire protection.

# Research

## ANNUAL REPORT OF THE COMMITTEE ON RESEARCH*

*To the Board of Directors:*

### 1. The Research Committee

In order to increase the activities and usefulness of the committee it seemed desirable to appoint working subcommittees to take charge of the several important divisions of the work. The following have been appointed:

Subcommittee on Placing of Research Subjects with Suitable Persons and Organizations—(D. W. Roper, Chairman).

Subcommittee on Training of Research Men—(V. Bush, Chairman).

The membership of the committee should be so chosen that a considerable percentage of the membership of the subcommittees will overlap from year to year. The appointment of several other working subcommittees is under consideration. It is hoped that the working committees of the Research Committee will eventually make it as effective in the research field as similar working committees have made the Standards Committee in the standardization field. It is suggested that consideration be give to changing the Research Committee from a technical committee to a standing committee.

### 2. Examples of Outstanding Research During the Year

The spectacular contribution to the communication art in the past year has been television. This has a particular interest from the standpoint of research since it was made possible by improvements in mechanical and electrical facilities that have sprung directly from research work, instances of which are improvements in photoelectric cells, in methods of amplification, in gaseous discharge lamps for producing visible effects from rapidly changing electrical signals, and improved methods of synchronization of widely separated points.

Other developments are the Knowles tube and its application to the televox, starting electrical equipment at a distance, and the development of a 50 million-cycle tube with a 10-kw. output. The increase in power of many American and foreign radio stations, making them international in their effects, raised the question as to whether or not the national standards of radio frequency of various governments were in agreement. During the past year a check was made by Dr. Dellinger of the Bureau of Standards in the National Laboratories of England, France, Italy, and Germany by means of the temperature controlled piezo-oscillator. The average difference was only 0.03 kilocycles in 1000. This is much smaller than the variation of 0.5 kilocycles allowed broadcasting stations in this country.

A radio beacon system establishing an invisible but infallible course along which aviators can fly regardless of weather conditions, has been sufficiently perfected by the Bureau of Standards so that routine use of it on regular airways is beginning.

A most impressive and historic event took place at the Winter Convention this year. Through the courtesy of the American Telephone and Telegraph Company and the British Post Office a joint meeting took place over the radio telephone between the Institution of Electrical Engineers of Great Britain meeting in London and the American Institute of Electrical Engineers meeting in New York.

There has been a number of researches during the past year of a fundamental nature. Particular mention might be made of the work of Davison and Germer regarding the diffraction of electrons by crystals of nickel. They prove that electrons behave at reflection as though they had wavelengths dependent upon their velocity. The discovery and measurement by J. B. Johnson of an electromotive force due to the thermal agitation within conducting materials is also of importance.

Among new tools which increase the scope of fundamental work in physics and engineering might be mentioned the operation by Coolidge of three cathode ray tubes in series at 900,000 volts.

A lightning generator producing impulses of over 3,500,000 volts also offers an important tool for the extension of fundamental work in physics and engineering.

Considerable important work on insulation measurements and lightning measurements on transmission lines is being carried out.

An analysis of the important fundamental research of the country shows that a fairly large percentage is still being done by the large industrial laboratories such as those of the American Telephone and Telegraph, the Westinghouse, and the General Electric Companies.

### 3. Research Organizations

While the large manufacturing companies are still doing a considerable percentage of the important fundamental research, there are indications that our colleges and other organizations will play an increasingly important part, as they should. It is reassuring that funds are more readily available than ever before.

*COMMITTEE ON RESEARCH:

F. W. Peek, Jr., Chairman.
H. D. Arnold,
Edward Bennett,
V. Bush,
E. H. Colpitts,
W. F. Davidson,
W. A. Del Mar
W. P. Dobson,
V. Karapetoff,
A. E. Kennelly,
S. M. Kintner,
M. G. Lloyd,
C. E. Magnusson,
E. W. Rice, Jr.,
D. W. Roper,
C. H. Sharp,
C. E. Skinner,
R. W. Sorensen,
J. B. Whitehead.

*Presented at the Summer Convention of the A. I. E. E., Denver, Colo., June 25-29, 1928.*

An important new factor in research has been given us in the Bartol Foundation, the result of a large bequest. Dr. Swann, director of this organization, which will undoubtedly have a very important influence on future American research, has kindly supplied the following information regarding it.

"The Bartol Research Foundation of the Franklin Institute is at present located in three houses at 127 No. 19 St., Philadelphia. These houses were made over a few years ago for laboratory purposes, and comprise ten research rooms, a library, glass blowing room, shop, and accommodations for storage battery equipment, etc.

"The present site is only temporary, pending the completion of a new laboratory. By an arrangement with Swarthmore College, it has been decided to build upon the campus of the college. By this arrangement the laboratory secures a site free from the disturbances of traffic and protected as regards its surroundings. It secures a congenial academic atmosphere such as most of its members have been accustomed to. On the other hand, while there is no affiliation to the college itself, the college feels that our presence will rebound to its advantage in many ways, and we hope and feel that this will be so.

"The laboratory will be about 110 ft. long and 50 ft. wide, comprising a basement, first and second floor, and a subbasement large enough to accommodate one spectroscopic room. The attic will also accommodate two rooms. The basement floor includes a large machine shop, wood shop, a glass blowing shop, and a battery installation, together with a room for miscellaneous technical operations.

"The first floor will be devoted to research laboratories and a workshop for the fellows, and the director's laboratory and offices. On the second floor there will be an apparatus room, a lecture room and large library, an optical shop, small office and research rooms, and the attic will provide for a chemical laboratory. The whole is designed to accommodate about ten or fifteen fellows together with the director, and research assistants. At the present time the technical staff comprises one instrument maker, one mechanic and an apprentice, also a full time glass blower and a general utility man.

"The main activities of the laboratory will be directed to the investigation of scientific problems pertaining to the fundamentals of electrical science. This is, of course, rather a wide field and comprises practically the whole field of modern atomic structure under its head.

"While the laboratory is primarily for research, it is proposed to provide in it such conditions for continued mental development as are desirable for young men of the post Ph. D. type. The director and the individual fellows take turns in lecturing to the group upon various phases of modern physics, particularly in relation to atomic structure. The Bartol Foundation has been fortunate in having many lecturers from American institutions, and a fund has been appropriated for the purpose of bringing from time to time distinguished physicists to stay here for a period of two or three months and give the laboratory the benefit of their intellectual contact.

"At the present time, the laboratory is accommodating six fellows on its payroll, one National Research Council fellow, a guest fellow, and one research assistant. It is possible that two or more National Research Council fellows will be here next year. Since October 1, 1927, eight publications of the Bartol Foundation have appeared in the *Journal of the Franklin Institute* and six publications of the results of investigations at the laboratory have been presented before the American Physical Society.

The following investigations are at present under way at the laboratory.

1. An investigation on the reflection of atoms of atomic hydrogen from crystal surfaces.
2. The production of, and characteristic properties of X-rays produced by protons.
3. An attempt to detect a magnetic field resulting from the rapid rotation of a copper sphere.
4. An investigation concerning the pulling of electrons out of metal under intense electric fields.
5. An investigation of the loss of velocity of electrons as a result of the production of characteristic X-rays in the passage of the electrons through thin metallic films.
6. A series of investigations pertaining to the mechanisms involved in the production of the electric arc between carbon electrodes and metal electrodes.
7. The design of an apparatus for the production of high electrical potentials.
8. A series of investigations having to do with the effect of high-frequency fields on optical and allied properties of transparent media.
9. An investigation of the nature of excitation of various lines in the mercury arc.
10. An investigation of the part played by cosmic radiation in the production of radio activity.
11. An investigation on the electrical conductivity of non-aqueous solutions of solvents.
12. A theoretical investigation on the scattering of X-rays by matter.
13. The preparation of a paper involving the results of observations of the cosmic radiation, made at Pike's Peak and New Haven."

* * * * *

The Public Utilities are entering the research field and are not only supplying money to colleges, but are also operating research laboratories. As an example, the Utilities Research Commission, made up of representatives of the utilities of which Mr. Samuel Insull is the head, has arranged for investigation of cable insulation at the University of Illinois, of lightning protection at Purdue, and of properties of insulation at the University of Chicago, etc.

Important work is being carried on in insulation by committees of the National Research Council, the N. E. L. A., etc.

The Research Committee of the Institute serves as the Advisory Committee on Electrical Engineering to the National Research Council and is also closely cooperating with the Engineering Foundation.

### 4. The Training of Research Workers

Results in research depend more upon men than money and laboratories. It is still a fact that in spite of organized research and group working in large laboratories, outstanding results are generally due to the genius or inspiration of the right man. While such men cannot be manufactured in our colleges, natural ability can be developed under the proper influence. Apparently the colleges are making progress, as indicated by the report of Professor V. Bush, Chairman of the Subcommittee on Training of Research Engineers, which follows:

"There is a considerable increase in the emphasis being placed on graduate study and hence on engineering research, which is an important part of such study, in schools of advanced standing among the technical educational institutions of the country. The total graduate enrolment in engineering colleges on the basis of the statistics of the United States Bureau of Education was 1114 in 1925-26, 1566 in 1926-27, and 1669 in 1927-28. The principal branches are civil, mechanical, electrical, and chemical engineering and in 1925-26 these four included 807 out of the 1114. During the three years cited the figures for civil engineering are 156, 240, and 266; those for mechanical engineering 256, 206, and 240; and those for electrical engineering, 281, 434, and 468. Of course these figures include many graduate students in technical schools where there is little important research being carried on; and perhaps only 30 or 40 per cent are in contact with research of a high order in their institutions. Still it is evident that there is an increasing tendency toward work of this nature in technical schools, and that this tendency is particularly marked in recent years among students of electrical engineering.

"It is believed that this tendency toward graduate study and research is a healthy development, and that its growth should be encouraged by industry and by the profession. Perhaps the greatest encouragement that can be given is for the students to learn that real achievement in advanced work is highly regarded by the profession wherever such is the case. There is no doubt that the recent analysis by the Bell System of the correlation between high grades in college and success in later work on their staff, as presented by President W. S. Gifford in Harper's Magazine for May 1928, will have a real vital influence in encouraging a scholarly attitude on the part of undergraduates generally. Similarly, if the industry and profession find by experience that graduate study of a serious sort is worth while for students of outstanding ability, the knowledge that such a conviction exists will be of the greatest value in raising the tone of graduate study and research in the engineering colleges. It is to be hoped, therefore, that the membership of the Institute will watch this development of graduate study and research with interest, and that, if they believe it is a desirable thing for the progress of electrical engineering, they will make known their convictions in an effective manner.

"Direct aid of such work by industries is, of course, valuable, particularly when the research carried on at educational institutions is carefully correlated with the regular instruction so that the full pedogogical benefit of working in a research atmosphere is obtained. Some years ago, for example, when graduate study in engineering schools was just beginning to grow, the American Telephone and Telegraph Company contributed directly to electrical engineering research at the Massachusetts Institute of Technology, and the work resulting was conducted in close liaison with the instructional program of that institution. The research results obtained were themselves worth while, but more important was, undoubtedly, the influence upon the student body and the early exposure of students to the research point of view.

"It is becoming increasingly evident in recent years that electrical engineering is adopting and applying more and more of mathematical and applied physics and chemistry. Hand in hand with this adoption must go the training of research workers of high calibre who have the engineering attitude, if the greatest progress is to be made. Industrial research is being well carried on by the industry, but the principal supply of research workers must come from the colleges; and, as electrical engineering becomes more and more complex, the training in advanced study and research in the technical schools must continue to expand as it has done in recent years to meet the need."

F. W. Peek, *Chairman.*

# Electrophysics

## ANNUAL REPORT OF THE ELECTROPHYSICS COMMITTEE[*]

*To the Board of Directors:*

The personnel of the Committee and its general policies have been practically the same as during the preceding Institute year, so that this report is essentially a continuation of the last year's report. A steady endeavor has been made during the year to connect some practical engineering problems with the achievements and efforts of modern physics, both experimental and mathematical. In these endeavors we have been materially assisted by the two liaison representatives of the American Physical Society, authorized by the Board of Directors in 1927. As a further step in the same direction, the committee arranged for a general lecture on *The Nature of the Electric Arc* which was ably delivered by Professor K. T. Compton at the 1927 Summer Convention in Detroit.

The success of this lecture led to an authorization of another lecture at the 1928 Winter Convention. The subject of this lecture was *The Earth's Electric Charge*, and it was delivered by Dr. W. F. G. Swann of the Bartol Research Foundation. This lecture was also quite successful, and as a result a lecture on geophysics, by Dr. C. A. Heiland, was presented at the Denver convention. The committee recommends that a lecture on some topic in "border sciences," such as physics, chemistry, mechanics, and mathematics, be scheduled at all our large conventions, as a stimulus to young engineers in fostering the progress of the art and as a preventative against in-breeding. In particular, for the next Winter Convention, the committee suggests a topic on spectrum analysis in application to the constitution of the stars. During such a lecture, much of the latest progress in the atomic structure could be explained on a specific problem.

### PAPERS PRESENTED

Quite a number of papers related to electrophysics have been presented at or scheduled for various Institute meetings during the period covered by this report. The titles and authors of several of these papers are mentioned below in connection with the individual topics. The papers themselves will be found in the JOURNAL and the TRANSACTIONS for 1927 and 1928.

### ELECTRICAL DISCHARGES IN GASES

*Disruptive Discharges.* A simple relation for determining the voltage across a spark-gap during the course of breakdown has been given, but the constant entering into this relation has been found to vary widely under different conditions of test. (Toepler, Mueller, *Arch. f. Elektrotech.*). Cathode ray oscillographic study of spark-gaps also gives results incompatible with the Toepler spark constant (Tamm, *Arch. f. Elektrotech.*). Photographs of incompleted sparks indicate the need for modification of the Townsend sparkover theory for high voltages at atmospheric pressures. (Torok, A. I. E. E. QUARTERLY, April 1928). The distortion of the electric field by a space charge in the early stages of the formation of the spark may be important (Loeb, *Journ. of Franklin Inst.*). Whether negative ions are generated near the cathode by collisions of positive ions with gas molecules, or by radiation acting photoelectrically upon the cathode, has been actively debated. (Taylor, Townsend, *Phil. Mag.*). Experiments on "three-point spark-gaps" favor the photoelectric action. (Morgan, Thomson, *Phil. Mag.*). Lowering of the sparking potential under sustained high-frequency applied voltage has been observed. (Reukema, A. I. E. E., TRANS., 1927).

*Corona.* Further studies on the mechanism of corona, bringing out the part played by space charges, have been made (Carroll & Lusignan, QUARTERLY TRANS. 1928, Peek, A. I. E. E.TRANS., 1927). A quantitative theory giving excellent checks with observations has been developed for the d-c. corona. (Holm *Arch. f. Elektrotech.*)

*Arcs.* There has been great interest in the theory of the electric arc. The possibility of arcs with cathodes too cold for thermionic emission is being accepted. Application of the heat balance method of determining the proportion of current carried by electrons from the cathode does not agree with the thermionic theory of the cathode. (Compton, A. I. E. E. TRANS., 1927). In applying the heat balance method, the experimental results of Van Voorhis (*Phys. Rev.*) on the heat of neutralization of positive ions are important. The view that electrons are drawn from the cathode by very high electrostatic gradients maintained by space charges is being favored (Compton, Prince, A. I. E. E. TRANS., 1927). In this connection, however, Rosario (*Journ. of Frank. Inst.*) describes experiments casting doubt on the ability of electric fields, of the order of magnitude here postulated, to draw electrons from a cold cathode.

### SHORT-TIME PHENOMENA

The study of transients occurring on transmission lines, with the aid of the klydonograph and surge recorder, has been actively pursued during the past year. Although much valuable information has been obtained, yet it is becoming increasingly apparent that more information is needed with respect to the form of the transients than the Lichtenberg figures have given.

A. P. Wills

*Presented at the Summer Convention of the A. I. E. E., Denver, Colo., June 25-29, 1928.*

The cathode ray oscillograph is the only device available which will give an oscillographic record of the volt-time relations of short-time transients. Norinder has applied the oscillograph to this work successfully. Additional work is being undertaken in this country so that valuable contributions along this line may be looked for in the next few years.

The study of lightning and of transients due to lightning still continues to occupy the interest of physicists and engineers. Several laboratories in different parts of the world are being equipped to study high-voltage transients. Crest voltages of over 3,000,000 volts have been reached. Spark-gap measurements, insulator flashover, strength of insulation, as in transformers, and the strength of wood poles, are some of the problems being actively studied.

Valuable research has been accomplished in connection with the protection of oil tanks and reservoirs against lightning strokes. Still more work is needed in order that the mechanism of the lightning discharge may be more fully understood. Some studies have been reported in which the mechanism of the breakdown of a sphere-gap and a needle-gap under transient conditions has been studied experimentally. (Torok, see above; Zinszer, *Phil. Mag.*, 1928). Additional research of this nature would be of great value.

### HIGH-VOLTAGE RESEARCH

Further study has been made during the past year of corona, using the cathode ray oscillograph. Valuable contributions with respect to the space charge of corona have been made. Last year marked the first 220,000 volt transmission to be installed in the East and this year this system has been considerably extended. Studies of lightning phenomena are being continued on this 220,000-volt system with the promise of obtaining useful data.

### FERROMAGNETISM

Among the advances which have been made in the field of ferromagnetism during the past year are the following:

1. Further studies of the magnetization and magnetostriction of single crystals of iron (Dussler and Gerlach) and of nickel (Kaya and Masiyama, and Sucksmith, Potter, and Broadway), show the dependence of these properties on crystallographic direction.

2. The permeability of iron has been reported in two papers (Wait, and Gutton and Mihul) to have no peculiarly small value in alternating fields of radio frequencies, contrary to the results of Wwedensky.

3. Magnetic viscosity, the time lag in magnetization, has been investigated experimentally by Lapp.

4. DeWaard in a mathematical treatment has attempted to account for ferromagnetic properties as dependent on crystal form and crystal lattice.

5. Some evidence has been obtained by X-ray analysis of films of iron in magnetic fields as to the ultimate nature of magnetism. T. D. Yensen, *Phys. Rev.*, Vol. 31, April 1928, p. 714.

6. An X-ray analysis of thin films of electrolytic iron gave results supporting the hypothesis of the atomic nature of magnetism. A circular X-ray diffraction pattern resulting from the randomly oriented minute crystals of iron in a film were examined with the film unmagnetized and also magnetized. No difference in the pattern due to magnetization could be detected, a result apparently explicable only on the assumption that the fundamental magnetic unit is atomic in character.

7. A notable contribution to the literature of ferromagnetism, of particular interest to electrical engineers, is T. F. Wall's book on Applied Magnetism.

8. A new method of obtaining strong magnetic fields has been described; P. Kapitza, *Roy. Soc. Proc.*, 115, Aug. 1927, p. 658.

9. A magnetic field within a coil of wire was produced by sending through the coil a current with amplitude in some cases as high as 72,000 amperes. As a source of current, a single-phase a-c. generator of the turbo alternator type was used, a half cycle only being utilized. A magnetic field within the coil, of about 320,000 gauss, was developed for about 1/100 of a sec. throughout a volume of 2 cu. cm. The chief difficulty encountered was in designing a coil to withstand the extremely large mechanical distorting forces of electrodynamic origin. Experiments on the change of resistance of bismuth due to a field of 300,000 gauss showed a thousandfold increase in resistance at the temperature of liquid air and a fiftyfold increase at room temperature.

### RADIO AND ELECTRO ACOUSTICS

The following were live topics during the year under review:

*A. Radio:*

1. Propagation phenomena; effect of solar activity, ionized regions, Heaviside layer, etc., on radio transmission;
2. Precision measurement of frequency;
3. Television without wires;
4. Radio on trains;
5. Miscellaneous apparatus, such as field intensity sets, tube generators, etc.

*B. Acoustic matters:*

1. Super-sonic waves in gases, liquids, and solids;*

---

*By super-sonic waves are meant longitudinal vibrations similar to sound waves, but of frequencies much beyond the audible range, reaching as high as 400,000 oscillations per second and beyond. Some striking effects of such waves, as well as practical applications, have been demonstrated by Prof. R. W. Wood of Johns Hopkins University.

2. Analysis of vowel and other sounds by means of technical devices;
3. Bessel and exponential horns for sound power;
4. Loudspeaker and receiver tests;
5. Sound transmission through building materials.

*C. Generation of Sinusoidal Sound Waves:*

A beat-frequency generator, for producing audio currents which are practically sinusoidal, has been constructed by the Bureau of Standards. The frequency is adjustable and stabilized by means of a piezoelectric quartz disk and can be directly read off on a scale. The holder containing the piezoelectric element has a hand control for changing the frequency of the quartz disk by a small amount (a fraction of a cycle to several cycles).

On account of the piezoelectric control, it is possible to reset the calibration for the frequency for most any useful *B* voltage on the tubes producing the two high-frequency currents which beat with each other. The resetting can be carried on without any standard, by means of a filament rheostat common to both oscillator tubes. The slow visible vibrations on the meter for the anode current of the piezoelectric oscillator are utilized for the resetting of the scale.

A thermostatic control is provided for very accurate work. Two filter detector circuits are provided for obtaining audio currents of a good wave shape and keeping any high-frequency currents away from the load branch. A specially designed power amplifier is available. The same is used when more energy is required.

## MAGNETIC AND ELECTROSTATIC FIELDS

Magnetic field distribution has been studied in application to various problems in electrical machinery, such as reluctance, wave form of e. m. f., pole-face losses, inductance, armature reaction, etc.

An important advance in our knowledge of magnetic fields is the work of Dr. Th. Lehmann. In the *Revue Générale de l'Electricité*, Dec. 24, 1927, he discusses the effects of pole saturation and interpolar iron on interpolar flux, considering as before the non-lamellar character of the field. The non-lamellar field, also treated in some recent articles in the *General Electric Review*, and *Electric Journal*, is related to eddy-currents, which were considered by Roth, Schenkhag, and Strutt. Roth has discussed the case of slot-conductors in the *Revue Générale de l'Electricité* of Sept. 27, 1927. H. Schenkhag and M. Strutt have discussed the flux distribution in busbar conductors, in the *Archiv für Elektrotechnik*. Dr. E. Weber, in the *Archiv für Elektrotechnik* of Nov. 17, 1927, has reported on the effect of the pole-shoe shape on flux distribution and wave form of e. m. f. Dr. Th. Lehmann has pointed out a needed modification of the "Minimum-Reluctance Rule" in computing mechanical forces of the magnetic field.

The electrostatic field of force within high-tension transformers has been investigated by Dr. J. Labus in the *Archiv für Elektrotechnik* for Nov. 3rd, 1927. The method used was that of the functions of a complex variable, and several new cases have been solved. W. Wittwer in the *Archiv* for April 7, 1927, reported on a combined mathematical and experimental method, by which he has studied the correlation between the breakdown strength and the geometrical factor, for the cases of insulation bounded by electrodes with sharp edges.

## DIELECTRICS

In view of the existence of a Committee on Electrical Insulation of the National Research Council (Professor J. B. Whitehead, Chairman) with which the writer of the present report has kept in close touch through several members common to both committees, the activities of the Electrophysics Committee in the field of dielectrics so far have mainly consisted in cooperating with the other committee. Those interested in details of various research projects and actual investigations in the field of dielectrics, should consult the Annual Reports of the Committee on Electrical Insulation. Among the principal problems under discussion are the following: (a) Dielectric phase difference, loss and absorption; (b) Ionization, polarization, and physical theories; (c) Dielectric strength and breakdown; (d) Dielectric constant; (e) Resistivity and conductivity; (f) Flashover; (g) Physical and chemical changes due to electric stress; (h) Properties of particular materials as related to manufacturing processes; (i) Special problems on the insulation of communication systems.

At the summer convention of the A. I. E. E. in Detroit, in 1927, a serial report of the Committee on Electrical Insulation covered the literature on Electric Strength of Solid and Liquid Dielectrics. During the past year there have been few contributions on this subject in American literature and the foreign press has contained a few articles. Apparently more attention is being given to other phases of dielectric behavior and to consideration of various series of dielectric phenomena. A serial report of the Committee on Insulation of the National Research Council prepared by Dr. Curtis covers the subject of electrical resistivity of insulating materials, and we have had a paper on the Theory of Imperfect Solid Dielectrics by Dr. Malti. Bush and Moon have reported on a device for automatically obtaining a large number of determinations of dielectric strength as a means of eliminating some of the uncertainties due to the wide variations between individual readings. This seems to offer considerable promise if applied to other materials than those studied by these authors.

A paper by Murnaghan throws additional light on the Boltzmann-Hopkinson principle of superposition as applied to dielectrics and is indicative of the attention which is being given in several laboratories to the phenomenon of absorption.

A considerable number of thorough-going researches are under way dealing with various phases of impregnated paper insulation as used in high-voltage cables, and the results of some of these have appeared in print as papers before the Institute, or those of rather more restricted circulation. This includes the paper presented by the Detroit Edison Company before the Association of Edison Illuminating Companies.

Joffé, at Leningrad, and some of his coworkers are studying dielectric absorption in its relation to polarization and conductivity of crystals. This work is very significant in its indication of the nature of dielectric absorption in some of its manifestations. He shows that in certain crystals there is an initial constant conductivity and that the final absorption phenomenon is due to a polarization which may be treated independently of the conductivity. Some of his coworkers have attempted to show that this initial conductivity is sufficient to account for the dielectric loss.

A number of experimental researches on dielectrics is being conducted at various universities, as will be seen from the following partial list:

Harvard University, under Prof. C. L. Dawes—"Gaseous Ionization in Impregnated Paper Insulation."

Massachusetts Institute of Technology, under Prof. V. Bush—"The Properties of Papers used for Impregnated Paper Insulation."

Johns Hopkins University, under Prof. J. B. Whitehead—"Influence of Variations in Drying and Evacuating Processes on the Properties of Impregnated Paper."

University of Wisconsin, under Prof. Edward Bennett—"Relation between Dielectric Losses and Anomalous Charging Current."

University of Illinois, under Prof. E. B. Paine,—"Ionization in High-Voltage Cables."

The Johns Hopkins University, under Prof. W. B. Kouwenhoven,—"Phase Difference in Air Condensers."

University of Wisconsin, under Professor Edward Bennett,—"Properties of Dielectrics."

The Johns Hopkins University, under Prof. J. B. Whitehead,—"Fundamental Study of Dielectric Absorption of Waxes and Oils."

Cornell University, under Professor V. Karapetoff,—"Study of Oils used in High-Tension Cables."

These researches are supported for the most part by the National Electric Light Association, Association of Edison Illuminating Companies, the Engineering Foundation, or individual public utilities.

### MECHANICAL SOLUTIONS OF ENGINEERING PROBLEMS

An Integraph has been developed by Professor V. Bush and his coworkers at Massachusetts Institute of Technology, for a mechanical solution of rather complicated differential and integral equations occuring in various branches of engineering. The machine has already been applied to several problems; for details see *Journal of Franklin Institute*, Jan. 1927, p. 63, and Nov. 1927, p. 575; also *Physical Review*, Feb. 1927, p. 337.

A mechanical device which quantitatively imitates electric transients in an interconnected power system, was described in a paper by R. C. Bergvall and P. H. Robinson at the Baltimore Regional Convention of the A. I. E. E., (QUARTERLY TRANS., July 1928).

### TEMPERATURE MEASUREMENTS

On May 12, 1927, the following resolution was passed by the Standards Committee of the A. I. E. E.: "That the broad question of standards for the technique of temperature measurement be referred to the Electrophysics Committee for investigation and report." In accordance with this request, the chairman has taken steps to ascertain the views of some interested parties and obtained a list of persons competent to serve on a subcommittee on Temperature Measurements. The problem is quite broad and the proposed subcommittee will have to investigate various methods of accurate temperature measurement, used in practise and in scientific work, find out their limitations and advantages, and select those which are sufficiently accurate without being unduly intricate. The chairman of this subcommittee has not been chosen as yet, but the matter has been submitted to the Bureau of Standards in the hope that a member of their staff may serve as chairman and thus be an impartial connecting link among the various industrial groups and scientific specialists represented on the subcommittee. It may be of interest to mention that there is a Committee on Heat Transmission of the National Research Council, and among its subcommittees there is one on Temperature Measurements. It is hoped that the proposed subcommittee will cooperate with this subcommittee.

### SOME POINTS OF CONTACT BETWEEN ELECTROPHYSICS AND ELECTRICAL ENGINEERING

A pure physicist usually studies whatever interests him most, or for whatever problem he has the necessary experimental and mathematical equipment. On the other hand, an applied physicist, or an engineer working on the border line between engineering and physics, is naturally limited to those topics which promise a more or less immediate application. The following list indicates some of such topics, although undoubtedly there are many more not included in it. It is hoped that this list may stimulate some younger engineers to undertake further "importation" of methods and results from the domain of physics into that of engineering.

*Arcs;* their theory, spectroscopy, phenomena at the cathode, stability, range of voltage, distribution of potential.

*Atmospheric Electricity;* theories of; methods of measurement; prediction of disturbances; thunderstorms, aurora borealis, ionized conducting upper layer of the atmosphere, the nature of terrestrial magnetism.

*A-C. Bridges*; various types, sources of power, detectors, inaccuracies, shielding.

*Bushings for Extra-high Voltages;* theory of stress distribution; design, experimental investigation of stresses, and safety against flashovers.

*Cables;* capacitance, heating, insulation resistance, ionization, study of oil and paper, stresses, joints, sheath and armor.

*Capacitance;* computation of, for lines, cables, plates, spheres, antennas, and irregular shapes. Measurement of capacitance in difficult cases; design of condensers for extra-high voltages and large capacitance.

*Cathode Rays;* their theory, production, measurements, application to oscillograph, penetration through matter, production of X-rays.

*Circuits;* general theory of; Heaviside's operational calculus; Carson's theories.

*Conduction of Electricity* in gases, liquids, and solids; fundamental theories, crucial experiments.

*Contact Phenomena;* resistance, e. m. f., heating, etc.

*Corona,* as a particular case of ionization and conduction in gases; study of the individual layers of ionized gas, from the electrode out; space charge, mobilities of ions, etc.

*Dielectrics* (topics discussed above).

*Discharges;* glow, brush, streamers, sparkover; their spectroscopy; character of ionization, numerical relationships.

*Electromagnetic Theory;* circuit equations, propagation of disturbances in dielectrics, dispersion; vector calculus operators; eddy currents in large conductors.

*Electrometers;* uses, theory, improvements in construction to facilitate setting up and use.

*Electrons and Positive Ions;* the fundamental properties: mass, charge, velocity, equivalence to a current, magnetic and electrostatic fields produced by such ions; action of external fields on an ion; relativity correction for mass; statistical mechanics of ions and neutral particles of matter in a mixture; reflection, ionization, diffusion, mobility, space charge; clustering; different kinds of collisions; refraction from crystals.

*Fields, Electric and Magnetic;* theory of fields, mapping out a field experimentally; theoretical plotting of lines of force and of equipotential surfaces; extension to three-dimensional problems.

*Heat conduction* in electric conductors and in dielectrics; accurate measurement of temperature distribution in electrical apparatus; theoretical investigation of heat flow in connection with iron loss and dielectric loss.

*High-Voltage Tests;* development of the technique of impressing a voltage of desired magnitude and wave form (steady, sinusoidal, impulse, etc.) and of accurately measuring its effect.

*Inductance;* measurement and theoretical computation of, for coils, lines, cables, and conductors of irregular shapes; effect of frequency.

*Lichtenberg Figures;* a detailed study of their production and properties; development of more sensitive figures which would clearly differentiate between the magnitude of an impressed voltage and its wave form.

*Lightning Protection;* development of laboratory tests for lightning arresters under conditions approximating actual service; measurement of actual line disturbances; production of materials and combinations with a smaller time lag, for lightning arresters; valve action; effect of a resistance in series with a protective device.

*Measurements* of amplification, current, frequency, voltage, power, phase angle, resistance, inductance, capacitance, time intervals, lengths, etc., when these quantities are extremely small, extremely large, of transient nature, or have to be observed under difficult conditions. Measurement of quantities introduced by the modern electronic physics, such as ionic currents, quanta, radiations, spectral lines, photoelectric effects, etc.

*Oscillations;* generation of electric oscillations; suitable circuits; theory of complex oscillations; the matrix theory of spectral lines.

*Oscillographs;* further development of types to extend the present range of usefulness.

*Photoelectricity;* theory of; measurement of the quantities involved; development of better photoelectric cells; new applications of such cells.

*Piezoelectricity;* theory, applications, apparatus, measurements.

*Quantum Theory.* This theory is the foundation of modern physics, and one not familiar with its premises and formulas is cut off from reading most modern books and periodicals in physics and from following the progress of the art.

*Spark-Gaps and Sparkovers.* Much remains to be done in ascertaining the behavior under various conditions of gas pressure, temperature, and moisture. A more rational theory, in terms of electronic ionization, photoelectric effect, and space charge is also needed.

*Spectroscopy* is proving to be a very powerful tool in various physical studies, so that it is of importance for engineers to become familiar with its methods, theory, and nomenclature, such as band and line spectra, arc and spark spectra, relative intensities of lines, superfine structure, terms, series, excitation by collisions and by radiations, etc.

*Structure of Matter.* The present knowledge of intra-atomic phenomena is in most cases insufficient to account for the complex phenomena with which engineers are concerned, making an empirical approach unavoidable. Nevertheless, a rapid progress is being made in atomic physics, and new methods and concepts are being introduced, such as quanta, relativity, the matrix theory, the wave mechanics (Broglie-Schroedinger), etc., so that engineers working on the border-line of physics should keep posted at least on the general trend of the progress, introducing new concepts and terminology into their work as much as possible.

*Thermionics;* emission of electrons from hot bodies; theory and methods of measurement.

*Transient Phenomena;* although the theory of many transients has been thoroughly investigated, yet there are many others of greater complexity or of shorter duration, for which we have neither a satisfactory theory nor proper recording devices.

*Vacuum Technique.* More and more electrical measurements have to be performed in a high vacuum or under reduced pressure, and it is of importance to continue developing pumps, pressure gages, temperature and moisture control, elimination of impurities, etc., to make such measurements simpler and more accurate.

*Waves and Surges* along wires and in dielectrics acquire greater and greater importance both in power engineering and in communication work. Their experimental investigation is for the most part quite difficult, for they are transients in time and in space, whereas our recording devices are stationary and measure transients in time only. The theory of such transients is also quite involved and requires a knowledge of some new and advanced branches of mathematics and physics. Nevertheless, the electrical profession as a whole will have to develop experts capable of dealing with such problems, and a concerted effort should be made without further delay, possibly beginning with the best colleges of engineering.

*Wave Mechanics.* At the present writing, much of theoretical atomic physics is being re-written on the basis of the so-called "wave mechanics," introduced by de Broglie and Schroedinger. If this point of view continues to be successful, the next generation of engineers may have to deal with concepts entirely different from ours. Even such well-established principles as electronic orbits within an atom, begin to be looked upon as mere abstractions of the human mind rather than physical realities. For a general exposition of this theory see H. F. Biggs, "Wave Mechanics," *Oxford University Press*, 1927; K. K. Darrow, *The Bell System Technical Journal*, 1927, Vol. 6, p. 653; W. F. G. Swann, *Journal of Franklin Institute*, 1928, Vol. 205, pp. 323 and 519.

*X-Rays.* The importance of X-rays in various industries increases each year, so that many more electrical engineers should become familiar with the theory of these particular radiations, as well as with the handling of the apparatus and specimens. Moreover, X-rays are proving to be a powerful means of studying the structure of matter, and the constitution of the atom, particularly in its inner parts adjacent to the nucleus, which latter remains the least known part of the atom.

VLADIMIR KARAPETOFF, *Chairman.*

# High-Frequency Measurements

## ANNUAL REPORT OF THE COMMITTEE ON INSTRUMENTS AND MEASUREMENTS*

*To the Board of Directors:*

The Committee on Instruments and Measurements is at present studying several pertinent phases of electrical measurements through standing subcommittees as follows:

1. Measurements of Variable Power and Large Blocks of Energy
2. Dielectric Power Loss and Power-Factor Measurements
3. Measurement of Non-electrical Quantities by Electrical Means
4. High-Frequency Measurements
5. Remote Metering

The present status of these is as follows:

### VARIABLE POWER AND LARGE BLOCKS OF ENERGY

This subject was covered in the report of the committee for 1925-26. Additional matter for future report is being collected by the subcommittee under the chairmanship of Mr. T. E. Penard.

### DIELECTRIC POWER LOSS AND POWER FACTOR

This subject was covered by symposium at the Niagara Falls Regional Meeting of the Northeastern District, May 1926. Additional matter is submitted in the following report by Mr. H. Koenig, subcommittee chairman.

In May 1926, a symposium on dielectric loss and power factor measurements was held at Niagara Falls. The symposium was called for the purpose of recording the then well-known methods of taking such measurements, probably as the first step toward standardizing such tests.

It is a difficult matter, of course, to determine just how effective the symposium was. It was the feeling of those who presented papers describing the various methods of making dielectric loss and power factor measurements that there was little hope of standardizing on any one method. The symposium did serve, however, to clear the atmosphere about these measurements and to point out the advantages and disadvantages of each method. It was also indicated at that time that a scheme for calibrating and checking the various methods now in use would be of great advantage.

Since the symposium, there have been two known advances in the line of checking dielectric loss equipments, particularly in the tests of underground cable. The first is the calorimeter method which was brought out in the discussion at the symposium by Mr. E. S. Lee of the General Electric Company. The second is the use of standard loads which have been developed at the Electrical Testing Laboratories. To the best of my knowledge, the only checking by the calorimeter method has been done by the General Electric Company in their own laboratories. A paper entitled *A Thermal Method of Standardizing Dielectric Power Loss Measuring Equipment*, by Messrs. J. A. Scott, H. W. Bousman, and R. R. Benedict, (A. I. E. E. QUARTERLY TRANS., July 1928) was presented at the Baltimore Regional Meeting of the Middle Atlantic District, April 1928, describing further comparisons using this method.

During the spring of last year a set of standard loads developed at the Electrical Testing Laboratories was used in an intercheck covering ten cable factories in the eastern part of the country. The result of this intercomparison was very satisfactory. It is hoped that some time in the near future a paper covering the tests will be written.

All other developments have been along the line of improving the technique of making measurements rather than the introduction of new circuits or methods. Neither has there been any further effort along the lines of standardizing on the method of testing.

Numerous articles have been published in some of the foreign technical magazines covering dielectric loss and power factor measurements. No new methods have been suggested nor have radical changes been made in the methods in use in this country.

The importance of proper shielding in making dielectric power loss measurements is becoming more generally realized. A paper presented by C. L. Kasson at the Pittsfield Regional Meeting of the Northeastern District, May 1927, entitled *High-Voltage Measurements on Cables and Insulators*,[1] emphasized the necessity of proper shielding. The subcommittee is planning to hold a symposium on this subject in the spring of 1929 dealing with the general subject of shielding both in dielectric power loss and other measurements.

### NON-ELECTRICAL QUANTITIES BY ELECTRICAL MEANS

This subject was reported in a paper by P. A. Borden published in the TRANSACTIONS of the A. I. E. E., Vol. XLIV (1925), p. 238, together with an accompanying bibliography. The compilation of the bibliography has been continued by Mr. Borden, a second supplement having been published with the report of the Committee on Instruments and Measurements for

[1] A. I. E. E. TRANS., Vol. XLVI, 1927, p. 635.

1926-27. A third supplement of the bibliography is attached to this report.

A study of the range of subjects in this bibliography shows the ever-increasing extension of the measurement of non-electrical quantities by electrical means. The number of the articles being published at present on this subject is too extensive for Mr. Borden to continue their compilation. Instead, a series of papers or lectures on the various subjects involved will be presented before the Institute. The lecture by Dr. C. A. Heiland on "Geophysical Methods of Prospecting" given at the Summer Convention, Denver 1928, is the first of this series.

### High Frequency Measurements

This subject was thoroughly treated in a symposium at the Pittsfield Regional Meeting of the Northeastern District, May 1927, a résumé of which was given in the report of the Committee on Instruments and Measurements for 1926-27. Due to the wide interest in this subject and the rapid change in technique it was thought desirable to have a member act as liaison officer with the I. R. E. Committee on the Determination of Circuit Constants. The I. R. E. Committee has prepared a list of references containing the various types of measurement and in addition has developed new methods particularly with reference to the measurement of inductance of several hundred henries such as found in audio frequency transformers and choke coils both with and without superposed direct current. The report of this work is to be published. Professor H. M. Turner, subcommittee chairman, has been active in this work.

### Remote Metering

The following report prepared by Mr. E. J. Rutan, subcommittee chairman, gives the results of answers to questionnaires relative to the present status of this subject.

The Instrument and Measurements Committee sent out questionnaires for the purpose of obtaining information on remote metering equipment now in use. These questionnaires were sent to a number of representative electric power companies, railroads, manufacturers, and public utility holding companies located both in this country and in Canada. From a total of 108 inquiries, 76 replies have been received as listed in Table I:

TABLE I

| Group | Classification | Number of Replies |
|---|---|---|
| A | Electrical Transmission of Electrical Measurements | 31 |
| B | Electrical Transmission of Mechanical Measurements | 10 |
| C | Remote Metering Equipment in Use, no Data Given | 3 |
| D | Prospective Users of Remote Metering Equipment | 6 |
| E | No Remote Metering Equipment in Use | 26 |
| | Total | 76 |

The purely electrical remote metering systems, as reported in the replies in group "A," can be classified into the ten distinct systems given in Table II.

TABLE II

Classification of Remote Metering Systems

| | | | |
|---|---|---|---|
| 1. | Voltage | 6. | Potentiometer |
| 2. | Impulse | 7. | Frequency |
| 3. | Position (induction) | 8. | Impulse Condenser |
| 4. | Inverse Current | 9. | Contact Integration |
| 5. | Current | 10. | Thermal Converter |

Referring to a paper on the *Automatic Transmission of Power Readings*, by B. H. Smith and R. T. Pierce, presented at the Midwinter Convention in Philadelphia, February 1924, it will be noted that the first seven types of systems listed in Table II were described in that paper. In the discussion that followed, the thermal converter type was also mentioned. The two systems not mentioned in the paper are not necessarily new. The contact integration system was mentioned in five replies and the impulse condenser was mentioned in two replies. Judging from the replies to the questionnaires, no new fundamental remote metering devices or systems have been developed since the presentation of the paper by Messrs. Smith and Pierce. The systems described in that paper will be given only a brief general description here but the other three systems will be described more in detail.

An attempt has been made to give an idea of the characteristics of operation and the accuracy of each method as it was reported. This was done in spite of the fact that nearly all of the users of remote metering equipment were compelled to report the performance of their systems under widely varying conditions. Certain systems whose inherent characteristics render them inaccurate due to interference from outside sources, can be made more reliable by the proper installation and shielding of the transmission line. It may also be noted that while the transmitter is often sufficiently accurate the receiver chosen to operate with it necessarily limits the accuracy of the system. This may cause the reported accuracy to be low, while a more accurate receiver would result in a more favorable reply. The importance of this point is evident when it is realized that many systems are classified according to the type of transmitter used without reference to the type of receiver. It is evident, then, that more definite information is needed to reconcile many of the apparently contradictory replies.

No attempt has been made to summarize the first cost and maintenance as no definite figures were given, and the replies received were evidently based upon the correspondent's limited knowledge of only a few of the systems in use.

*1. Voltage.* In this system the voltage supplied to the receiver is varied by a potentiometer which is operated by an instrument measuring the quantity desired. Some types are varied by a Kelvin balance or relay type graphic meter. The indications are transmitted over supervising wires, pilot wires, or pressure wires to a voltmeter type indicating or graphic meter.

The chief advantage of this system is its simplicity. Obvious disadvantages are its sensitiveness to changes in line resistance and the necessity for close regulation of the supply voltage.

A few companies reported the reading of voltage directly over distances from a few hundred feet to two miles.

*2. Impulse.* This method seems limited to watthour type meters in which impulses proportional to the speed of the meter are sent out to receivers where polarized relays actuate an escapement. Dials geared to the escapement record the power being measured.

This method has the advantage of being positive in its action and quite independent of line conditions. The distance over which this system may be used seems to have no definite limit, the greatest reported distance being 200 miles. Some disadvantages are the intricate type of receiver necessary, a delicate transmitter which is likely to introduce errors, and the possibility of being affected by static disturbances. The reported accuracy seems to range from "fair" to plus or minus one per cent of full scale deflection.

*3. Position.* This method employs two similar a-c. induction motor units in which the rotor of the receiver closely follows the movements of the rotor of the transmitter.

This system is very simple and requires little or no attention. It is also very reliable, positive in action, and comparatively independent of line conditions. The line resistance limits the distance over which operation is possible, the limiting resistance being about 3000 ohms.

This method has the disadvantage of requiring five wires for operation. It is also reported that the transmitter needs a powerful operating torque, thus making it necessary to use more powerful instruments. It is sometimes necessary where a number of large receivers is connected together, to make use of power amplifying relays and motors.

The reported accuracy of this system as given by one manufacturer is two per cent of full scale deflection.

*4. Inverse Current.* This method makes use of a motor operated rheostat, controlled by the indicating or recording meter, which simultaneously adjusts the circuit resistance and the counter torque on the instrument. The receiver is a recording or indicating ammeter which receives current inversely proportional to the load.

An outstanding advantage of this method is the ease with which any number of indications may be totalized by connecting the rheostats of each meter in series. The resultant current is then inversely proportional to the total load.

The chief disadvantage lies in the complicated design and wiring necessary. The precision is also reported as being low or only fair.

*5. Current Balance.* This method is similar to the inverse current method except that the rheostat is connected to a Kelvin balance type of meter and the resultant current is directly proportional to the load. The receiver may be an inverted transmitter or an indicating or recording ammeter.

These instruments may be placed in parallel and the totalized current is then proportional to the total load. This method seems quite widely used, 9 replies reporting satisfactory operation of this system. One manufacturer reported 31 users of this system, 5 of whom replied to the questionnaire. Seven users of method reported transmission distances of at least 3 mi. and up to 24 mi.

The accuracy appears to be good, some stating that it depends on the choice of a receiver.

*6. Potentiometer.* The potentiometer type may also consist of a Kelvin balance type meter which controls a motor operated rheostat, but in this case it is the line voltage which is varied. The receiver may consist of motor operated rheostat controlled by a contact making voltmeter; or as reported in one letter, a milliammeter is used.

One of the advantages of this system is that the calibration is not materially affected by a change of line resistance. Another advantage is that a telephone line may be used for transmission. This method was reported in use on lines up to 56 mi. in length. The accuracy is reported as "fair" and probably depends on the choice of equipment.

*7. Frequency.* This is a complex system in which a Kelvin balance type of meter is made to control the frequency of a small a-c. generator. At the receiving end a frequency meter is used, calibrated to read load power. This system is easily adapted to totalize any number of readings. The control of apparatus may also be effected.

This system does not seem suitable for customer installation due to its complex nature, involving as it does elaborate apparatus and requiring constant attention. When used by a company that uses and distributes large blocks of power over considerable distances, the excellent results that are obtained would seem to warrant its installation.

*8. Impulse Condenser.* In this novel system, contacts on several meters are momentarily made to connect a condenser to a charging circuit, and the receiving instruments perform a measurement upon the rate of discharge of this condenser through a resistance. This system was used over lines 3½ mi. long.

The accuracy of this system seems to be low. The information received for this method is meager, but little seems to be said in its favor.

*9. Contact Integration.* This system may consist of contacts operated by a watthour meter, wherein the total number of contacts made over the system is totalized on a recording instrument, or the contacts made by demand meters are recorded at one point on one instrument. The greatest reported distance of transmission was 5 mi., but this range may be extended by the use of suitable relays.

The accuracy of this method seems to depend upon the type of transmitters and receivers and the amount of local interference. Accuracies from one to two and one-half per cent were reported.

This system apparently gave satisfactory service in four out of five reported cases, while the fifth correspondent reported a failure due to induction from a nearby high-voltage line.

*10. Thermal Converter.* The important unit in this system is known as a thermal converter, and consists of two heating elements so connected to the instrument current and potential transformers that the temperature difference of the two elements is proportional to the watts in the metered circuit. Thermocouples are placed in this converter in such a manner that the "hot" junctions are associated with one heating element and the cold junctions with the other. The resultant thermoelectric potential is proportional to the difference in temperature of the two heating elements and is therefore porportional to the watts or power in the circuit. It was found possible to design the thermal converters to give a linear characteristic over the range used, and thus allow the units to be connected in series, when it is desired to totalize loads from a number of sources.

The accuracy of this method seems to lie in the receiver, which is usually a high-grade recording potentiometer, when accuracy may be of the order of one-half of one per cent. Thus a null method of measurement is used which practically eliminates any possible effect due to changes in line resistance. Indications have been transmitted successfully up to 8 mi. over telephone and supervisory lines. Other reported advantages are the lack of moving parts in the transmitting unit and the complete reversibility of the converters. This latter feature permits the use of this method on tie feeders where a reverse of power may occur.

This is the only new type of system developed since 1922 which has come to the attention of the committee. Arrangements are being made for the presentation of a description of this system before the Institute.

### CONCLUSION

It is still the feeling of the subcommittee that sufficient operational data have not yet been submitted to allow conclusions to be drawn as to the accuracy of the remote metering systems in use.

### ADDITIONAL SUBJECTS

In addition to the work being carried on by the standing subcommittees as reported above, there are several other subjects which the committee are working upon as the following:

### SYSTEM DISTURBANCES

There is a growing demand for recording instruments for switchboard application to record the variation of current, voltage, and power with time during system disturbances. In this connection a symposium was held jointly by the Committee on Protective Devices and the Committee on Instruments and Measurements at the New Haven Regional Meeting of the Northeastern District, May 1928, at which time two series of papers were presented, one describing available instruments for making these measurements and the other giving the experiences of the operators in the use of these instruments. This symposium was under the direction of Mr. R. T. Pierce for the Committee on Instruments and Measurements. The papers presented under the auspices of this committee were:

*Hall High-Speed Recorder*, by C. I. Hall*

*Pages from the Hall High-Speed Recorder*, by E. M. Tingley†

*Oscillograph Recording of Transmission Line Disturbances*, by J. W. Legg†

*High-Speed Graphic Voltmeter*, by A. F. Hamdi and H. D. Braley.*

### REVISION OF ELECTRICAL UNITS

Following the presentation by Dr. E. C. Crittenden at the Summer Convention of the Institute, Detroit, 1927, of a paper entitled *The International Electrical Units*, a resolution was presented and passed that the matter of the revision of the electrical units should be referred to the Committee on Instruments and Measurements for their consideration and study. This has been done and resolutions have been prepared and transmitted to the Board of Directors through the Standards Committee, urging the United States Bureau of Standards and other foreign national standardizing laboratories to undertake the necessary researches to eliminate the present discrepancies between the legally established electrical units and the absolute units which they were intended to represent, and to urge the legalization of absolute units.

### MEASUREMENT OF CORE LOSSES IN TERMS OF SINE-WAVE CORE LOSSES

The Committee on Instruments and Measurements has been asked to investigate and report on the best way to make core loss measurements so that they will give accurate sine-wave core losses regardless of the wave form employed for excitation. This subject is being studied by a working committee under the chairmanship of Mr. W. M. Bradshaw.

### DISTORTION FACTOR—DEFINITION AND METHOD OF MEASUREMENT

The Committee on Instruments and Measurements has been asked to give consideration to the adoption of a definition for distortion factor and methods of test, as disclosed in a report of the French Electrotechnical Commission entitled "Methods of Determining the Distortion of the Voltage Wave of Alternators." This matter is being considered by a working committee under the chairmanship of Mr. W. M. Bradshaw.

†A. I. E. E. QUARTERLY TRANS., Vol. 47, No. 4, Oct. 1928.

### ACKNOWLEDGMENT

It is but fitting that we recall at this time the contribution in the past to the work and activities of this committee by Mr. J. R. Craighead. Mr. Craighead was appointed Chairman of the Instruments and Measurements Committee at the beginning of this year but he was removed from us by sudden death November 22, 1927. In his passing there have been lost to us the contributions of an active and energetic worker, and the advice and counsel of a scholar.

EVERETT S. LEE, *Chairman.*

## Bibliography

### MEASUREMENT OF NON-ELECTRICAL QUANTITIES BY ELECTRICAL MEANS

Note: The first supplement of this Bibliography is published in the TRANSACTIONS of the A. I. E. E., Vol. XLIV, 1925, p. 238.

The second supplement is published in the TRANSACTIONS, Vol. XLVI, 1927, p. 709.

The third supplement is given herewith.

# Electrical Communication

## ANNUAL REPORT OF COMMITTEE ON COMMUNICATION[*]

*To the Board of Directors:*

The Committee on Communication submits the following report as a summary of the progress which has been made in the electrical communication art during the past year.

### PRINTING TELEGRAPHS

There has been continued growth in the use of printing telegraph instruments. In addition to the applications for police service mentioned under another heading, the volume of commercial message and similar traffic handled by such instruments shows a steady gain, both on long and short circuits. As an example of the latter, it may be noted that more than 800 circuits connecting main and branch officers of the telegraph companies are now equipped with printers.

The tendency to reduce manual operations as much as practicable has been quite pronounced in ocean cable telegraphy during recent years. As a result, printing telegraph equipment is now employed on both long and short cables in many cases. Recent developments in this direction were described in a paper entitled *Printing Telegraphs on Ocean Cables* which was presented by H. Angel at the 1927 Summer Convention of the Institute.

The automatic tape transmission system for telegraph tickers which was mentioned in the 1926 and 1927 reports has been further extended during the past year, so that full market quotations are now available to practically all sections of the United States.

### TELEGRAPH REPEATERS

Many of the repeaters now used on long telegraph circuits, both in land line and ocean cable service, are of the regenerative class. In such repeaters, automatic means are employed to retransmit practically perfect signals although the received signals may be so badly distorted that with earlier forms of repeaters the retransmission would be far from perfect. A description of one type of regenerative repeater and an outline of operating experience with it was given in A. F. Connery's paper on *A Non-Rotary Regenerative Telegraph Repeater* presented at the 1927 Summer Convention.

Rather important advances have been made in the simplification of circuit and equipment arrangements for telegraph repeaters installed in central telegraph offices.

### TELEGRAPH TRANSMISSION THEORY

A paper entitled, *Certain Topics in Telegraph Transmission Theory* was presented at the Winter Convention of the Institute by H. Nyquist. In addition to presenting a quantitative statement of certain fundamental telegraph requirements, this paper presented for the first time an analysis of the fundamental problems involved in single sideband carrier telegraph transmission which may offer important economies in frequency range under some conditions.

### CORD CARRIERS FOR TELEGRAMS

For some years past, most large telegraph offices have been equipped with mechanical conveyors, usually of the moving belt class, for the transfer of telegrams from one part of the operating room to another. A multiple cord carrier system has recently been developed which is proving very satisfactory for such conveying service. Where delivery to two or more points is necessary, the cord carrier equipment costs much less than the equivalent flat belt equipment. The power required to operate a three-channel cord system is no greater than that needed by a single-channel flat belt. Other advantages of the cord equipment are increased speed, reduced maintenance expense, minimum interference with lighting, and complete visibility at all points, thus facilitating inspection.

### DIAL TELEPHONY

The rapid application of dial telephone systems has continued. During the year, about 500,000 dial telephone stations were installed, bringing the total in service in this country, as of the first of January 1928, to approximately 2,900,000 stations or about 16 per cent of the total telephones in service.

A paper entitled *Some Recent Developments in Dial Systems*, by W. E. Farnham and H. M. Bascom, was presented at the Student Branch Convention and Sectional Meeting in New York in April of this year.

The dial system of operation has been extended to service from one suburban point to another suburb of the same city. This matter was discussed in a paper entitled, *Tandem System of Handling Toll Calls in and About Los Angeles*, by E. Jacobsen and F. D. Wheelock, which was presented at the 1927 Pacific Coast Convention.

### TOLL TELEPHONE SERVICE

During the year, telephone toll service was established between the United States and a number of important cities in Mexico, including Mexico City, Tampico,

*Presented at the Summer Convention of the A. I. E. E., Denver, Colo., June 25-29, 1928.*

Monterey, Saltillo, San Luis Potosi, Puebla, and others. The service was inaugurated by an exchange of greetings between President Coolidge and President Calles at the capital cities of the two republics over a circuit 3360 mi. long. The service from Mexican points was further extended to points in Canada by the end of 1927.

The various connections of the United States telephone network to important cities in Canada were augmented during the year by the completion of a circuit from Bismarck, North Dakota, to Regina, the capital of Saskatchewan.

A substantial improvement was made in the handling of toll calls, especially by increasing the percentage which are handled while the subscriber remains at the telephone.

### TELEPHONE TOLL CABLES

The extension of the network of toll telephone cables throughout the country continued at an increased rate during the year 1927, about 2000 mi. of cable being installed. Important additions included the completion of a route from Albany to Cleveland through Syracuse, Rochester, and Buffalo; the extension of the cable south of Washington to Petersburg, Virginia; and an extension from Chicago to Terre Haute, Indiana. In addition, a toll cable between Buffalo and Hamilton is approaching completion and another between Toronto and Oshawa is being started. This supplements the existing Toronto-Hamilton cable and provides a connection between the toll cable system in Canada and the great system in the United States.

At the present time, 7,500,000 telephones of the Bell System have direct access to the toll cable network in the northern and eastern parts of the country which provides within that area toll service which is relatively immune from the effects of storms.

### PLANNING EXTENSIONS TO TELEPHONE PLANT

The problems involved in the planning of telephone plant and descriptions of the telephone plant in various regions were discussed in a number of papers presented at Institute meetings. The principal papers were as follows: *Advance Planning of the Telephone Toll Plant*, by J. N. Chamberlain, presented at the Pacific Coast Convention; *Telephone Toll Plant in the Chicago Region*, by Burke Smith and G. B. West, presented at the Chicago Regional Convention; and *Planning Telephone Exchange Plants*, by W. B. Stephenson, presented at the St. Louis Regional Meeting.

### COMMUNICATION APPARATUS AND MATERIALS

The application of permalloy to communication problems continued during the year. Interesting information regarding this material was given in a paper entitled, *Manufacture and Magnetic Properties of Compressed Powdered Permalloy*, by W. J. Shackleton and I. G. Barber, which was presented at the Winter Convention.

A paper entitled, *Recent Developments in the Process of Manufacturing Lead-Covered Telephone Cable*, by C. D. Hart, was presented at the Chicago Regional Meeting.

### ELECTRICAL TRANSMISSION OF PICTURES

While no new stations have been added to the telephotography network of the Bell System (Boston, New York, Atlanta, Cleveland, St. Louis, San Francisco, and Los Angeles), interest in the service is increasing greatly and it is becoming much more important to the press.

### TELEVISION

At the last annual meeting in New York a talk on television was given by Dr. H. E. Ives, followed by a demonstration at the Bell Telephone Laboratories. A symposium on television at the Detroit Summer Convention was led by Dr. Ives and also was followed by demonstrations. The symposium included notable papers entitled: *The Production and Utilization of Television Signals*, by F. Gray, J. W. Horton, and R. C. Mathes; *Synchronization of Television*, by H. M. Stoller and E. R. Morton; *Wire Transmission of Television*, by D. K. Gannett and E. I. Green, and *Radio Transmission of Television*, by E. L. Nelson.

### CARRIER-CURRENT AND SUPERIMPOSED SYSTEMS

During the year there was a marked increase in the use of carrier-current systems in commercial telephone and telegraph plant, including a new system of a simplified nature which provides a single channel and is applicable economically to distances as short as 75 mi. The total length of carrier telephone circuits added during the year was approximately 65,000 channel mi.

In the application of carrier telegraph arrangements over 125,000 two-way channel miles were added to the Bell System during the year. This includes channels obtained from open-wire facilities by carrier frequencies above the voice range as well as voice-frequency carrier telegraph channels obtained from circuits in long toll cables. The increase is approximately evenly divided between the two types.

The application of carrier-current telephony to communication over power lines has increased steadily until, at the present time, there are in this country alone, 298 fixed stations in operation. Recent improvements in these systems have been along the lines of interconnecting them with private telephone systems. Portable and semi-portable carrier communication apparatus is being successfully used in conjunction with fixed stations. The large majority of these installations provide duplex operation, each system on a single frequency. The transmitter output is in the order of 50 watts, in the majority of the fixed installations; this power is proving adequate for usual conditions. As the demands for increased channels are made, the need of reducing the width of the communication channel without sacrificing understandability becomes more imperative.

Utilization of carrier current for other than communication purposes is rapidly increasing. The applications are for control of street lights, pilot protection of transmission circuits, supervisory control of substations and similar equipment, telemetering, etc.

Certain power companies are now using devices to operate graphic indicating meters at a distance, by means of d-c. impulses carried over signal circuits. By this arrangement, an operating supervisor or system operator may see at any moment the amount of power that is being fed into the system from generating points located at various places in the area covered by the power system. The total load taken by a town or city at some point may also be recorded at the system operating center.

Some recent developments in carrier current and other superimposed systems were described in the following papers presented at Institute meetings during the year:

*The Use of High Frequency Currents for Control,* by C. A. Boddie, Summer Convention 1927.

*A Carrier-Current Pilot System of Transmission Line Protection,* by A. S. Fitzgerald, Pacific Coast Convention 1927.

*Coupling Capacitors for Carrier-Current Applications,* by T. A. E. Belt, Pacific Coast Convention, 1927.

### SUPERVISORY CONTROL APPARATUS

In the power field, elaborate supervisory and control arrangements are now available by which an operator can control switches or other apparatus at distant points, and by means of currents transmitted back from the distant point determine the conditions which exist there. The Westinghouse Company reports that development work is being started on a form of such supervisory control apparatus, which is of interest in the communication field as it is intended to operate at frequencies in the voice range which can be transmitted over telephone circuits. The work has not yet reached the point where the possibilities and limitations of the system can be determined. Demonstrations of a preliminary model of the apparatus under the name "Televox" have, however, created considerable popular interest from the fact that the operation of such an arrangement over telephone circuits can be thought of as simulating conversation between persons.

### TRANSATLANTIC RADIO TELEPHONY

The opening of transatlantic telephone service between the United States and England was covered in last year's report. The service was improved by the completion of a radio receiving station at Cupar, Scotland, which is located as far north as conveniently possible for the purpose of reducing interference caused by atmospheric disturbances.

The time during which service normally is available has now been extended to 14½ hr., the period of service extending from 5.30 a. m. to 8.00 p. m., eastern standard time. The service was extended to Cuba and to five cities in Canada as well as to various cities of Continental Europe.

The outstanding event which took place during the period covered by this report was the holding of a joint meeting of two organizations on opposite sides of the Atlantic for the first time in history. This was a joint meeting of the Institute during the Winter Convention in New York with the British Institution of Electrical Engineers in London.

Preliminary to the joint session, a paper entitled, *Transatlantic Telephony—The Technical Problem,* was presented by O. B. Blackwell, and a paper entitled, *Transatlantic Telephony—The Operating Problem,* was presented by K. W. Waterson.

The joint session was preceded by the opening of communication from New York by Mr. Charlesworth who spoke to Colonel Lee in London. The telephone was then turned over to President Gherardi and to President Page of the British Institution of Electrical Engineers. After an exchange of greetings, brief addresses were given by Dr. F. B. Jewett and General John J. Carty from this side of the water and by Colonel Purves and Sir Oliver Lodge from London.

At various times during the year the transatlantic telephone service was discussed at a number of sectional meetings.

### INTERNATIONAL RADIO CONFERENCE

The International Radio-Telegraph Conference held in Washington in 1927 achieved several very important agreements affecting international radio communication. The delegates were faced with the responsibility of expanding an agreement made several years ago, mainly with a view to facilitating the use of radio in marine communication service. Since that agreement had been written, the use of radio had expanded to telephone as well as telegraph service and the field had widened to embrace in addition to the marine communication services, aids to navigation such as compass and beacon, aircraft and other new mobile services, point-to-point services, amateur and experimental work, and broadcasting. The new agreement had to apply to this much wider field of use without hampering the progress and development of the art. The most important achievements were the following:

The agreement on the assignment of frequency bands for services in the whole radio spectrum.

The recognition of the fact that every type or method of transmission of necessity occupies a definite frequency band or channel.

The agreement that interference to other services is the controlling limitation put upon the method of using a frequency channel.

The recognition of the amateur status in the international communication field.

The progressive suppression of the use of damped waves. No new installations using damped waves may be set up for land and fixed stations and the use of such waves at existing stations is forbidden after January 1, 1935. On ship and aircraft stations, new damped wave installations may be made only if such apparatus uses less than 300 watts on full power, and the operation of these damped wave installations is forbidden after January 1, 1940. Thus in 12 years the history of damped waves will close.

The agreement upon the use of an automatic alarm signal in the marine service.

The setting up of an International Technical Consulting Committee.

### RADIO BROADCASTING

Comparisons of results obtained by operating a broadcasting station with power outputs up to 100 kw. have established, fairly definitely, the essentials of this important subject.

Of considerable importance in connection with the performance of a high-power broadcasting station is the choice of site. Some locations are appreciably better than others, which indicates need of careful investigations before choosing a site.

Utilizing high-power tubes which recently became available, a 100-kw. transmitter has been developed which combines the essentials of all modern practises.

Since the previous report of this committee was made, two commercial 50-kw. broadcasting stations have been placed in operation.

Short-wave broadcasting and re-broadcasting in the U. S. and foreign countries has developed gradually with considerable recent improvements. These are mainly due to the utilization of sufficient power to provide dependable service and to improvements in the reception of short waves which have been almost exclusively used for this purpose.

Recent demonstrations of transmissions and receptions of both still pictures (facsimile) and moving objects (television), utilizing broadcasting transmitters, have indicated the probable future extensive application of these features to the present broadcasting service.

### OTHER RADIO COMMUNICATION

During 1927 short wavelengths were first utilized to provide a commercial service designed to maintain contact between the home office and ships making around-the-world tours. Such a service was applied also to ships plying between the United States and the far East where the distances are very great.

The percentage of long distance communication handled by short waves increased further during 1927. In the United States there were installed on several long distance radio circuits, the Radio Corporation of America's projector system. This system has been in use a sufficiently long period to demonstrate that it is a large factor in making it possible to obtain an economical long distance radio communication service. This projector system includes not only directive transmission but also directive reception. The directive reception differs from the transmission in that several receiving antennas directive in themselves, are spaced in such a manner as to eliminate the momentary fading which previously had so limited the use of short waves. With this method of receiving short waves it is possible to obtain a record so free from mutilation as to be practically perfect. Thus, in a way not anticipated some years ago, there has been accomplished the elimination of the effect of static.

The development and application of radio transmissions to aid in guiding aircraft has made rapid progress during the year.

Railroad train radio telephone equipment has been developed for front-to-rear communication on long freight trains. The apparatus provides telephonic communication and call signals between the locomotive and the caboose under all conditions whether the train is standing or in motion, and even when the train is broken if the separation does not exceed four or five miles. A four months test of the equipment was recently successfully completed on the James River Division of the Chesapeake and Ohio Railroad.

For cases in which the expense of the above mentioned telephone system cannot be justified, a signal system of lower power has been developed for service between front and rear of long freight trains. It provides only for call signals and telephonic communication is not possible. In operation a cord similar to a whistle cord is pulled, and a loud high-pitched signal is produced at the opposite end of the train. The range of this system is not over four miles.

Radio telephone equipment for railroad hump-yard service has been developed to facilitate the classification of freight cars at congested terminal points. The apparatus is similar to the train radio-telephone equipment, except that it is of lower power. The apparatus provides one way telephonic communication between the yard-master's office and any locomotive in the yards. The apparatus is operated the same as any telephone, and its range is limited to about two miles.

### SOUND REPRODUCTION

Improvements were made in the design of loudspeakers as regards efficiency, power, and uniformity over the speech frequency range. Some of the advances in design by which these improvements have been obtained were discussed in a paper entitled, *Loud Speakers of High Efficiency and Load Capacity*, by C. R. Hanna, presented at the Winter Convention, (A. I. E. E. Quarterly TRANS., Vol. 47, April 1928) and in a paper entitled, "A High Efficiency Receiver for a Horn-Type Loudspeaker of Large Power Capacity," by E. C. Wente and A. L. Thuras which was published in the *Bell System Technical Journal* for January 1928.

A paper entitled, *Electrical Reproduction from Phonograph Records*, by E. W. Kellogg, presented at the Detroit Summer Convention, discussed some interesting mechanical and electrical problems encountered in the development of improved reproducing devices.

### FIRE AND POLICE SIGNAL SYSTEMS

Further refinements of apparatus have been introduced in fire alarm systems during the past year. Improved automatic repeaters have recently come into use, the operation of which closely accords with the rules of the National Fire Protection Association requiring complete non-interference between coincidental signals, so that succession devices in street boxes will function, whether the boxes are on the same or on different circuits of the system.

In a new type of puncturing register the paper punchings are folded under instead of being detached, thus eliminating much objectionable paper dust; the instrument requires less power for its operation and runs at a higher speed than earlier registers.

Another improvement is the use of radio for communicating from fire alarm headquarters to moving apparatus, such as fire chiefs automobiles or fire boats. Boston has had such a broadcasting station for the past two years. It operates on a short wave, and has been found highly effective in sending orders to fire boats when absent from their regular berths. New York has recently experimented with a similar system.

In police signaling, an important development is the increasing use of telautographs and telegraph printers for interstation communication. These systems have been found useful in quickly and accurately spreading the news of hold-ups, automobile thefts, and other crimes. They have been found especially valuable where used in connection with the flashlight system of calling the patrolmen to the street signal boxes. A rather extensive installation of printing telegraph instruments made during the past year for the New York Police Department illustrates the expansion of service of this character. This system is so arranged that an operator at headquarters may send signals from a keyboard to any one precinct, to any group, or simultaneously to all precincts, the messages being printed automatically in page form at receiving machines placed close to the desks of officers in charge of precincts. Facilities are provided so that the receipt of the message may be acknowledged by each station. Another interesting system of this kind is in Connecticut, where police headquarters in twelve important cities are interconnected by telegraph printer circuits. It is expected that by the end of 1928 the system will be so extended that practically all of the cities in the state will be covered.

Several conflicting tendencies are noted in traffic signaling, particularly with respect to the colored lights or equivalent devices employed. While the green-amber-red cycle of signals has been adopted by many cities, others have favored either more or less complex arrangements. Centralized control of the street signals is being extended and while difficulties are experienced in so synchronizing operations as to minimize hazards and delays, it seems likely that this problem will ultimately be solved.

The blinker signals for outlying locations or crossings where there is little congestion are quite effective, particularly when equipped with Fresnel lenses. The gas type of blinker signal, using a tank of compressed gas for supplying the light jet has been superseded in many cases where electricity is available by a type using electric lamps.

H. W. DRAKE,
*Chairman.*

# Production and Application of Light

## ANNUAL REPORT OF THE COMMITTEE ON PRODUCTION AND APPLICATION OF LIGHT*

*To the Board of Directors:*

### INTRODUCTORY

The following report of the Committee on Production and Application of Light, as on former occasions, consists chiefly of a résumé of the more notable achievements of the year in the art of lighting by electricity. It has been compiled from information supplied by members of the committee and by other authorities in their respective fields who have kindly cooperated with the committee.†

## Production of Light

Most developments during the past year in the production of light have taken the form of refinements of design and adaptations of existing types of illuminants rather than of radically new methods or principles of light production.

### INCANDESCENT FILAMENT LAMPS

*Small Multiple Lamps.* Within the past year a new and smaller 10-watt tungsten filament lamp for 110-, 115-, or 120-volt service has been placed upon the market. This lamp has a bulb 1⅜ in. in diameter, designated "S-11" and a new base termed "intermediate," which is approximately ⅝ in. in diameter and ¾ in. long, standing in dimensions between the medium screw base and the candelabra base. This is a new size in the group of multiple lamps. It has been developed for places where physical limitations make the use of lamps of previously existing standard types difficult or impracticable. It is designed to yield an average life of 1500 hr. at a rated efficiency of 7.85 lumens per watt. It is available in coated bulbs in any of seven colors, the coatings being of a nature to withstand outdoor service. This lamp is expected to find wide use, especially in electric signs of the smaller sizes, in the design of which it has been difficult to achieve artistic effects with lamps of larger physical dimensions. Other uses to which the new lamp lends itself are outdoor decoration as of Christmas trees and illumination of small lighted ornaments which have recently appeared on the market for interior home decoration. It may also find application in the extension of cove lighting to residences where it has been extremely difficult to adapt this method of illumination due to the physical dimensions of the lamps heretofore available.

Another new lamp employing the intermediate base has recently been developed and placed upon the market in a bulb designated C9-¼. This lamp is rated at 10 watts, 115 volts and is designed to yield an average life of 600 hr. at a rated efficiency of 8.95 lumens per watt. It is intended primarily for lighting of Christmas trees and is available in coated bulbs in any of seven colors. Fig. 1 shows the two new intermediate base lamps in comparison with the 10-watt S14 medium screw base sign lamp.

In addition to these new lamps employing the intermediate base, the 15-watt flame shape bulb decorative lamp for 110-, 115-, and 120-volt service, formerly fitted with candelabra base is now available also with intermediate base.

A complete line of sockets and adapters for intermediate base lamps is now upon the market, as well as strings of seven sockets wired in multiple for Christmas tree and other decorative lighting.

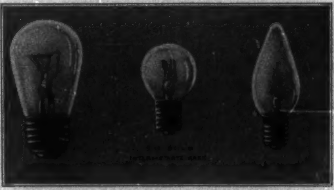

FIG. 1—10-WATT MULTIPLE LAMPS

*Very Large Lamps.* The successful production of incandescent lamps in sizes up to the 10-kw. lamp marks a distinct advance in the art of lamp manufacture and prepares the way for even larger sizes if they shall be needed. These extremely large lamps are manufactured for special purposes such as the lighting of aviation fields and motion picture studios. These applications are still in the developmental stage, though many installations are functioning satisfactorily.

*Projection Lamps.* A new development in the manufacture of incandescent lamps of the smaller sizes for projection purposes is the use of the "coiled-coil" filament by means of which the over-all dimensions of the light source are materially reduced, an object which is much sought in light projection. The resulting increase in uniformity and intensity of screen illumination has been a considerable factor in the growing popularity of home motion picture projection.

In certain types of concentrated filament lamps for light projection, more accurate and automatic positioning of the filament is attained through the use of a prefocused base consisting of a separate sleeve attached to an unthreaded base shell after the lamp has been otherwise finished.

†See list of non-member contributors on page 12.

*Presented at the Summer Convention of the A. I. E. E., Denver, Colo., June 25-29, 1928.*

The over-all dimensions of filaments of 750- and 1000-watt lamps for general service have been reduced in the interest of improved accuracy of light projection in flood lighting and of better distribution in the case of high-mounted industrial reflectors.

*Street Railway Lamps.* Two new lamps in inside frosted bulbs have been made available during the past year for street railway service. One of these is a 36-watt vacuum type coiled filament lamp designed for operation five in series on circuits of from 525 to 650 volts. The other is a low voltage, gas-filled lamp designed for operation at 30 volts per lamp, with approximately 20 lamps in series on the street railway circuit. This lamp has a special device incorporated in the lead-in wires by means of which the circuit is reestablished in case of the failure of the lamp filament. Being designed for low voltage operation, it has a relatively short and heavy filament and is therefore relatively sturdy; being of the gas-filled type and having a comparatively heavy filament, its light output per watt consumption is 40 to 50 per cent greater than that of the clear bulb, straight filament, vacuum type lamp designed for like service.

*New Large Bases.* In order to strengthen the attachment of the base to the bulb in the case of certain of the very large sizes of lamps, a Mogul screw base has been developed which, in addition to the cemented joint, has a mechanical clamp around the neck of the bulb.

For heavy current lamps taking more than 25 amperes and operating in the base down position, there has been standardized a two-prong base which is designed to overcome heating difficulties due to current density and contact resistance experienced with former types of bases.

*Short Circuiting Device.* To extinguish the arc which may be formed upon the failure of the filament in the smaller street series lamps and to maintain a closed series circuit, the lead-in wires have been brought into close proximity for a certain distance. If the arc travels along the lead wires the globules of metal on the ends of the two wires unite and short circuit the arc before it has an opportunity to damage the base of the lamp and the socket.

*Carbon Lamps.* Though the use of carbon filament lamps shows a decrease each year, the numbers of these lamps which are still in service and the numbers which are sold each year are very large. Carbon lamps seem to be particularly popular in colored bulbs and in bulbs of special decorative or novelty types. For purposes of illumination their use is, of course, uneconomical, but for decorative use they appear to meet a certain small demand.

*Operating Voltages.* The standardization of lighting circuit voltages continues to show progress from year to year. It is estimated by the lamp manufacturers that at the present time in this country 94 per cent of the population within reach of electric service is in territories served by some one standard voltage (110, 115, or 120) and that more than 99 per cent is within territories served by one or more than one standard voltage, leaving only a fraction of one per cent distributed among the odd voltages between 100 and 130. The voltage used most generally is 115. It is estimated that 59 per cent of the population within reach of electric service is provided with electricity at this voltage.

### SEARCHLIGHTS

The trend of development of military searchlight design since the war has been toward greater beam candlepower, lighter weight, greater mobility, and improved methods of control. There were two important developments in 1927.

One of these was the incorporation in the searchlight unit of a comparator system which makes it possible for the searchlight to be guided from a distance by accurate data transmitted electrically from a sound-locator station to the searchlight station. In anti-aircraft defense the pointing of the searchlight at the target is thus greatly facilitated.

The other development was the successful production of a 60-in. mobile searchlight unit employing a 250-ampere high intensity arc operated by a 25-kw. generating unit, and developing 1,385,000,000 maximum beam candlepower.

In order to facilitate signaling, searchlights of the smaller sizes in the Navy are being adapted to the employment of the incandescent lamp. Similar signaling searchlights using 1000-watt projection lamps have unique advantages in the submarine service in that the pressure on the projection drum may be equalized by allowing water to enter the unit.

### GASEOUS CONDUCTOR LAMPS

*Sign Types.* The neon tube lamp for display and sign service has grown in popularity during the last few years. By the use of various mixtures of gases and also by the employment of fluorescent glass tubing a number of color effects is obtainable, though some of these are not entirely stable at the lowest temperatures attained in the northern part of the United States. These signs require for operation a relatively high voltage and are characterized by a low power factor (usually below 50 per cent) when supplied with alternating current. On the other hand the efficiency of light production of the orange-red neon tube sign is relatively high and the guaranteed service life is long.

The vivid color contrast with daylight offered by neon tube signs tends to promote their use in daytime as well as at night.

*Hot Cathode Lamps.* The hot cathode neon lamp, a very recent development in this field, consists of a glass tube similar in form to that of the mercury vapor lamp now in general use, but filled with neon gas. The discharge through the gas is started and facilitated by the heating of the cathode. By this means the voltage drop at the electrode is reduced from 250 to 30 volts, making possible the operation of the lamp directly on a 115-volt a-c. or d-c. circuit. In this lamp the absence of electrode disintegration permits the passage through the tube of a comparatively large current with a resultant high intrinsic brilliancy and candlepower. It has been tried with some success in the illumination of opal letter signs, in the marking of pier heads and aviation fields and, in the form of a close spiral mounted at the focus of a parabolic reflector, as an airway beacon. It may be noted that this new form of neon lamp may be used in combination with the mercury vapor lamp to produce with high efficiency, light which is apparently white in color and which is expected to find application in color and panchromatic photography.

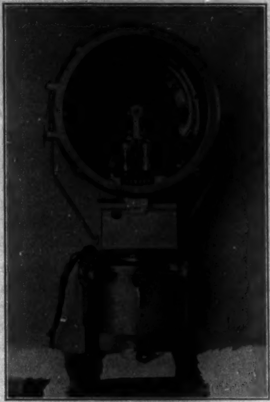

Fig. 2—Neon Induction Beacon

*Negative Glow Lamps.* The negative glow socket type neon lamp (known as the G10 indicator lamp) which was mentioned in the 1926 report of this committee has undergone further development during the past year. The present form of this lamp is designed for operation on 115-volt a-c. circuits. It consumes about one-third of a watt and emits somewhat less than one-tenth of a candlepower. Its field of use is primarily that of an indicator or night lamp. The corresponding lamp for d-c. service is under development but is not yet available.

*Television Lamp.* A prominent position in the recent successful demonstrations of television has been occupied by a neon lamp of a type specially designed for that class of service. The neon lamp is uniquely adapted to that purpose by virtue of its instantaneous response to variations of voltage.

*Induction Lamp.* The electrodeless discharge in neon, in the form of the induction lamp has recently been employed experimentally as a light source for airway beacons. The bulb enclosing the luminous gas is of clear fused quartz about 1½ in. in diameter and is mounted at the focus of a searchlight reflector. A short wave pliotron oscillator mounted in the reflector housing generates the high frequency current necessary to excite the gas within the bulb. Due to its orange-red color the neon induction beacon illustrated in Fig. 2 is said to excel in visibility at a distance in both clear and foggy weather when compared with other sources of equal beam candle-power.

## APPLICATION OF LIGHT

## Interior Illumination

### INDUSTRIAL LIGHTING

The year has witnessed advances both as to the general standards of industrial lighting and the extent to which modern methods are employed.

The industrial activities referred to in last year's report have undoubtedly secured a wider recognition of the value of good illumination in promoting workers' welfare and safety as well as speedy and economical production.

A survey of a considerable number of industrial plants on the lines of one of the largest electric service companies showed that on the average the electrical energy consumed for lighting approximately equaled that used for power purposes. Since this lighting service company has been particularly active for over a decade in promoting industrial lighting, the lighting of these plants is presumably better than would be found in most cities. But even allowing for this, the results indicate a more intensive use of light than would generally have been expected.

The Department of Labor and Industry, State of Pennsylvania, has adopted regulations for emergency lighting of places of public assembly and places where persons work after darkness. The rules call for an emergency illumination of at least half a foot-candle on the floor at exit doors, hallways, etc., leading to outside building exits, and of at least a quarter foot-candle on the floors of auditoriums. Control of the supply must function without dependence upon manual operation. The source of energy must be separate from that of the main lighting system, and when secured from outside the building must be supplied by two generating stations, an approved automatic throw-over switch being required.

### COMMERCIAL LIGHTING

Though the past year has been marked by no outstanding development in commercial lighting practise, it has seen a more widespread application of illumination due to a better appreciation of its utilitarian and advertising value. While the present practise in the majority of stores and offices is to provide general illumination with diffusing glass enclosing globes, there is a growing demand for lighting equipment of the semi-indirect type. In the main corridors of the newest office buildings and in hotel lobbies unique luminaires designed along the lines of modernistic art have appeared. These innovations in design not only provide an interesting variation but it is thought that they may lead to radical changes in types of commercial lighting equipment.

In the lighting of window displays the tendency has been to advance to higher intensities as the level of street illumination has risen and as the number and brilliance of electric signs have increased. The use of colored lighting and the employment of spotlights to create striking contrasts have been practised extensively during the past few years.

The more general use of color matching units is notable. Unfortunately such applications are peculiarly liable to misunderstanding and misrepresentation, both of which have been present to no small degree. Practise in artificial daylighting is in need of clarification.

## RESIDENCE LIGHTING

*The Modernistic Trend in Lighting Equipment.* For several years European artists and designers, notably the French, have been striving to develop a style which will express twentieth century tendencies. Their work has influenced furnishings of all kinds, including lighting fixtures. These modernistic fixtures usually employ plane rather than curved surfaces and strong, pronounced lines. Color is used to advantage and there is remarkable absence of unnecessary applied decorative bits. Almost without exception exposed bare lamps find no place in this equipment. The lamps are generally hidden from view, the light being diffused by some external medium.

The modernistic movement is beginning to find its way into American homes and it is to be anticipated that it will have considerable effect on home lighting practise. Already a number of progressive American manufacturers is showing some excellent fixtures in this new spirit. Two wall units and a unique table lamp of domestic manufacture are illustrated in Fig. 3.

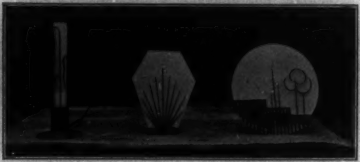

Fig. 3—Luminaires in the Modernistic Spirit

*Use of Light for Ornament.* Mention was made in last year's report of the development abroad of artistically lighted pieces of decoration. These lighted ornaments in general furnish no useful illumination, but give touches of high light in color about a room. They have been very aptly termed "the jewelry of the lighting installation." In the past year a great number of these devices has been imported and sold by the leading shops here. The tremendous potential field in America, however, cannot be covered by importations, and one of the leading American manufacturers has placed on the market a line of such ornaments, several of which are shown in Fig. 4.

Fig. 4—Lighted Ornaments for Household Decoration

*Residence Wiring.* The increasing cost of residence wiring and the growing tendency toward unreasonable restrictions in the use of materials and methods are believed in certain quarters to be serious hindrances to the development of the residential use of electricity. As a result of this feeling study has been devoted during the last few years to the problem of surmounting these obstacles in the way of household electrical development.

It is believed that there are three important factors underlying the undesirable conditions mentioned. These factors are, first, lack of adequate skill in planning the average residence wiring system; second, lack of economical wiring materials; and third, the tendency to employ the electric wiring codes as obstructions to new development and progress.

The first condition is being corrected in many localities through the employment by the central station companies of home lighting experts and by the propagation of the so-called "Red Seal" plan. Looking forward to the amelioration of the other two unfavorable influences there is considerable agitation for the development of lighter and less expensive wiring materials, and for the modification of the electrical codes if necessary to permit the use of such materials.

## THEATRICAL LIGHTING

The growing importance of stage lighting in dramatic production has led to the institution of a course in stage lighting in the Department of Drama at Yale University. This is perhaps the first serious attempt to teach lighting as a part of dramatic production. The course, which is open to students of some experience, involves a comprehensive study of the science of lighting particularly from the standpoint of history, physics, psychology, electricity, illumination, instruments, and control. This is followed by the study of the use of light on the stage and by practise on regular productions.

*Motion Picture Lighting.* The almost universal use of panchromatic film and the closer attention to operating efficiencies and economies are two principal factors which have brought about in some studios the substitution of incandescent lamps for other illuminants. It has been found that the spectral quality of the light from incandescent lamps is well suited to panchromatic film and by their use better color rendition is obtained than with other illuminants. It is stated that by the use of incandescent lighting the labor and power costs for lighting are considerably reduced and, further, that it is found to be more flexible, more easily controlled, and more pleasing to those working under it than are other systems. Producers of the so-called talking pictures have found incandescent lighting desirable in order that the noises of arc lamps may not be recorded.

The usual lighting requirements for motion picture production call for a general illumination of from 200 to 500 foot-candles over the entire area to be photographed and, in addition, concentrated beams of from two to five times these values for modeling the principal actors or for bringing out certain parts in contrast with the rest of the set. The larger sizes of incandescent lamps up to those of 10-kw. rating are used.

One of the recent developments in equipment for amateur motion photography is a portable reflector containing a standard 500-watt, T20 bulb, 100-volt projection lamp to be operated on the usual 115-volt house lighting circuit. This over-voltage operation, while reducing the average life of the lamp from the normal figure of 50 hr. to about 5 hr., greatly increases the amount of light produced as well as its actinic value and renders possible the use indoors of amateur motion picture cameras which have heretofore been dependent upon outdoor illumination.

During 1927 there has been developed and placed on the market a new type of motion picture projector which utilizes a 60-ampere high intensity arc with an ellipsoidal reflector as optical condenser equipment. With this new type of projector it has been possible to obtain screen brilliancies equivalent to those previously obtained with a 120-ampere high intensity arc and the usual condenser lens system.

## Exterior Illumination

### STREET LIGHTING

A tendency which has recently become evident in street lighting practise is the supply of 20-ampere series lamps from 20-ampere series circuits instead of through the medium of individual transformers from circuits carrying small currents. Besides the elimination of the individual transformers, this practise results also in the loading of the series conductor more nearly to its capacity and in the reduction of the voltage for which it must be insulated.

A method of remote control for street lighting circuits employing high frequency carrier-current impulses transmitted along the same conductors as the power current has been developed. The principal advantage of this method of remote control is that the power conductors are utilized for the transmission of control impulses without interference with their own function and without need for additional control conductors. It possesses a high degree of flexibility and is not subject to limitation of distance between transmitter and receiver to the same extent as is a pilot-wire control system. The first practical installation of the carrier-current control system was made in Schenectady, N. Y. Later installations have been made in Bayonne, N. J., Rochester, N. Y., San Francisco, Calif., and Boston, Mass.

### RELATION BETWEEN STREET LIGHTING AND MOTOR VEHICLE HEADLIGHTING

Obviously there is a close relation between street lighting and motor vehicle headlighting. The practise in either field affects that in the other field.

If adequate street and highway lighting were everywhere available, there would be no necessity for powerful headlight beams. Since it is not likely to be economically practicable to illuminate all roads over which motor vehicles travel, there is no likelihood at present of eliminating such equipment.

On the other hand, as adequate lighting of streets and highways becomes more extensive, the practicability and desirability of driving for a considerable part of the time with dimmed or deflected headlighting is becoming more and more possible of realization.

Powerful headlights, such as are necessary to illuminate a highway, are subject to serious limitations. The known methods of eliminating glare from the eyes of other users of the highways are only partially effective and are not universally applied. Such glare is a source of discomfort and hazard. On densely traveled highways, the continual subjection of a driver's eyes to one headlight after another becomes quite serious.

Engineers who have given the most thorough study to the problem have reached the conclusion that its solution lies in the fixed lighting of highways carrying heavy traffic, and assert that suitable lighting is available and economically practicable in many such situations.

While the glare from automobile headlights is less serious in well lighted streets and highways, it is still objectionable, and since the use of powerful beams is unnecessary under these conditions, it is desirable to encourage the practise of avoiding their use.

The Committee on Street Lighting of the Illuminating Engineering Society has sought the cooperation of the Committee on Motor Vehicle Lighting of the same society in the consideration of this question. As a result of the joint deliberations, the following resolution has been accepted as representing the views of both committees:

"JOINT RESOLUTION ADOPTED MARCH 7, 1928, BY ILLUMINATING ENGINEERING SOCIETY COMMITTEES ON STREET LIGHTING AND MOTOR VEHICLE LIGHTING

"RESOLVED, that in the opinion of the Illuminating Engineering Society Committee on Street Lighting and of the Illuminating Engineering Society Committee on Motor Vehicle Lighting, powerful headlights on automobiles as used in open road driving are unnecessary and undesirable upon adequately lighted streets. Upon such adequately lighted streets the practise of dimming or depressing headlight beams is desirable and should be encouraged.

"It is further the opinion of these committees that it is practicable at this time to provide such adequate street light for traffic thoroughfares of American cities. In general, street lighting on such thoroughfares is believed to be adequate for this purpose when the street area between curb lines is illuminated to an average horizontal intensity of one-quarter foot-candle or more. This illumination can be obtained even under unfavorable conditions by an expenditure of about 100 lumens per linear foot of street. Where light is applied most effectively, and other conditions are favorable, a materially smaller value of generated lumens will produce adequate illumination and will suffice for driving with dimmed or depressed headlight beams."

## AUTOMOBILE HEADLIGHTING
